If the decision is taken to treat the child, and there is no specific therapy available, then the backbone of empirical treatment is systemic steroids. If there are no facilities to confirm a specific diagnosis through lung biopsy, or the child is judged too sick for the procedure, then blind treatment may be justifiable. Indeed, some authorities treat all patients blindly, reserving biopsy for the steroid nonresponsive cases. One preferred (nonevidence based) regime is pulsed intravenous methyl prednisolone 10 mg/kg on 3 successive days every 4 weeks, combined with hydroxychloroquine 10 mg/kg and azithromycin 10 mg/kg, both once daily. One could use this regime for 6 months in the first instance. Children with severe ILD may mandate maintenance prednisolone (0.5 mg/kg on alternate days) between pulses, tapering as the disease permits. As an alternative to pulsed methyl prednisolone, oral daily prednisolone 2 mg/kg/day can be used, tapering the dose where there is a response. If there is no response to these steroid based regimes, empirical trials of cytotoxics such as methotrexate or azathioprine, or biologicals such as rituximab may be attempted. There is no role for inhaled corticosteroids.

Childhood ILD for which there are Specific Treatments

- *Hypersensitivity pneumonitis*: The key is identification of the allergen and prevention of exposure, in addition to steroid therapy (pulsed or oral, as earlier).

- *Sarcoidosis*: The antitumor necrosis factor- α (TNF- α) monoclonal infliximab, combined with methotrexate, may be effective.
- *Pulmonary alveolar proteinosis*: If due to anti-GM-CSF auto-antibodies, then inhaled or subcutaneous GM-CSF is effective, albeit expensive; whole lung lavage, which may need to be repeated on multiple occasions, may also work well.
- *chILD secondary to rheumatological conditions* may respond to specific regimens, e.g., cyclophosphamide for granulomatosis with polyangiitis (formerly known as Wegener's granulomatosis).
- *Idiopathic pulmonary hemosiderosis*: If bleeding is not controlled on the nonspecific regime above, consider triple pulses of intravenous immunoglobulin, intravenous cyclophosphamide and methyl prednisolone. Plasmapheresis can be used if acute bleeding continues despite steroid pulses; again, there is not much evidence for this.

Monitoring the Response to Therapy

There are no known biomarkers specific to chILD, and no guidelines on how to monitor the disease. If the child is old enough to perform lung function tests, and these are available, then spirometry may be used. Otherwise, oxygen requirement is a useful parameter, including the extent and speed of desaturation in room air. Repeat HRCT may be used to help judge the need for repeated lung lavage in pulmonary alveolar proteinosis, but otherwise is probably not as useful as physiological parameters.

Family Support

The family's anxieties must be understood; there may be a need for counseling or emotional support. They may need help in managing expectations in terms of the long-term prognosis. All parents feel scared and anxious about the future of chILD but with effective communication, fears can be faced. There must be a support system for the family, and an established point of contact if things are going wrong. If one is available, refer early to a pediatric respiratory specialist. The overall holistic care of the child, focusing not just on the disease, but the child and family, is a key role for all pediatricians. Finally, put the family in touch with others; if there is no national support group, the UK (<https://childlungfoundation.org>) and the USA (<http://www.child-foundation.com/>) have excellent parent support groups which can help families who are feeling alone and isolated.

OUTCOME

It is often very difficult to give an accurate prognosis, because most series of individual conditions are very small. So for example *Sp-C* mutations have a very variable phenotype, ranging from severe neonatal respiratory distress to usual interstitial pneumonitis in late middle age. Thus caution is indicated. Outcome of few specific conditions is as follows:

- **NEHI:** Oxygen dependency may be prolonged for many years, but eventual resolution should be anticipated. There may be persistent airflow obstruction, unresponsive to asthma medications.
- **PIG:** Prognosis is good, but deaths have been reported in preterm babies with this condition.
- ***Sp-B* mutations:** Although very rare, partial deficiencies with a good prognosis have been described, in general most die or have to be transplanted within a few months of birth.
- **Other *Sp* mutations:** As a general rule, the earlier the presentation, and the more severely ill the child, the worse the outlook.
- **Acute hypersensitivity pneumonitis:** If allergen exposure can be controlled, these children are usually steroid sensitive and a good recovery can be anticipated. However, if a fibrotic stage has been reached, then stabilization rather than recovery is the best that can be hoped for.
- **Pulmonary hemorrhagic syndromes:** The prognosis is very unpredictable, and even severely ill children may go into remission.

PREVENTION

There are no primary preventive strategies for chILD. Secondary prevention can be achieved in genetic chILD by termination of future affected pregnancies if this is acceptable to the families, and prevention of allergen exposure in cases of hypersensitivity pneumonitis.

IN A NUTSHELL

1. Childhood interstitial lung disease (chILD) comprises a rare and disparate group of more than 200 different entities.
2. Pathologically, chILD may result in filling of the alveolar spaces; and inflammation and fibrosis in the interstitium of the lung and the distal most airways.
3. Etiology in the first 2 years of life primarily consists of diffuse developmental disorders, neuroendocrine cell hyperplasia of infancy (NEHI), pulmonary interstitial glycogenosis, surfactant protein (*Sp*) gene mutations, and pulmonary alveolar proteinosis.
4. After 2 years of age, causes of ILD include *Sp* gene mutations, follicular bronchiolitis, lymphoid interstitial pneumonia (LIP), hemosiderosis, hypersensitivity pneumonitis, sarcoidosis, Langerhans cell histiocytosis and pulmonary alveolar microlithiasis.
5. Presentation is nonspecific. The most common presenting symptoms and signs are hypoxia, tachypnea, retractions, gastroesophageal reflux, pulmonary hypertension, cough, crackles, wheeze and failure to thrive.
6. HRCT chest, *Sp* gene mutation, lung function testing, Echo, CT, and bronchoscopy help in making the diagnosis. The ultimate diagnostic procedure is lung biopsy, usually VATS or via a mini-thoracotomy. Transbronchial biopsy is not recommended.
7. The backbone of empirical treatment of chILD is systemic steroids.

Chapter 39.26

Hemoptysis and Alveolar Bleeds

Meenu Singh, Nandini Paul

HEMOPTYSIS

Hemoptysis is defined as the coughing up of blood or blood-streaked sputum from the respiratory tract because of hemorrhage in the lungs. The criteria for categorization of hemoptysis are not well-established, yet it can be categorized as nonmassive or massive depending upon the amount of blood loss. Blood loss of 200 mL/day is categorized as massive hemoptysis and is considered as life-threatening. The diagnosis of hemoptysis in younger children becomes difficult because of their inability to expel out the sputum. The most common causes of hemoptysis in children are bronchiectasis, fungal infections and tuberculosis (**Table 1**). In European population, the most common predisposing factor for hemoptysis is cystic fibrosis.

ALVEOLAR BLEEDS

Alveolar bleeds refer to alveolar hemorrhage, a rare state of the airways, in which blood is infiltrated at multiple sites into the alveoli. The synonymous terms include: pulmonary alveolar hemorrhage, diffuse pulmonary hemorrhage, pulmonary capillary hemorrhage, microvascular pulmonary hemorrhage or alveolar bleeding. It is usually associated with anemia and hemoptysis but at times these conditions may be absent.

Localized pulmonary hemorrhage is a similar clinical condition which must be distinguished carefully. Accumulation of red blood cells (RBCs) originating from the alveolar capillaries into the alveoli is the characteristic feature of alveolar hemorrhage. On the other hand, localized pulmonary hemorrhage is confined to a particular region of the lung. Hemoptysis, a condition most often associated with alveolar hemorrhage, may not be present always but it should be tracked by bronchoalveolar lavage analysis with worsening RBC count. The condition may get worsened requiring ventilation and radiographic procedures.

EPIDEMIOLOGY AND ETIOLOGY

The prevalence of pulmonary hemorrhage in neonates has been found to be 7–10% upon postmortem examination. The incidence of pulmonary hemorrhage in live births is 1 out of 1,000. The etiology of the alveolar hemorrhage includes both immune-mediated and nonimmune-mediated disorders. The lungs are supplied by two

circulatory systems: the bronchial circulation is a high-pressure circuit arising from aorta and supply blood to the terminal bronchioles, whereas the pulmonary circulation is a low-pressure and high-capacitance circuit that arises from the right ventricle and perform gas exchange. The hemorrhage due to any of these circulation systems can be the result of multiple causes and may be localized or diffuse. Acute lower respiratory infection is the most common trigger, responsible for almost 40% of cases. Respiratory infections cause inflammation of the mucous membranes resulting into the breaking of the blood vessels. In children, airways infection with viruses, bacteria, fungi (aspergilloma) and parasitic diseases may also lead to hemoptysis. Hemoptysis due to tuberculosis is not as common in children as in adults but can be seen among adolescents with fibrocavitary disease. Children with cystic fibrosis often present with hemoptysis because of severe chronic airway inflammation that ultimately leads to progressive bronchiectasis and increased dilatation and fragility of bronchial vessels in the airway walls. Moreover, bronchiectasis related to other complications such as primary ciliary dyskinesia or immunodeficiency can also lead to bleeding. Colonization of the airways with microbes exacerbates these underlying diseases and forceful cough contributes to bleeding. Pulmonary hydatidosis is another important cause for hemoptysis.

Lung anomalies like pulmonary arteriovenous (AV) malformations, pulmonary telangiectasia, congenital absence of pulmonary veins, sequestrations also present as hemoptysis. Neglected congenital cyanotic heart disease cases like tetralogy of Fallot may present with hemoptysis due to rupture of large intrapulmonary collaterals. Severe mitral stenosis can also present with breathlessness and hemoptysis and is usually seen with poorly managed rheumatic heart disease.

Hemoptysis should not be confused with the bleeding from the upper digestive tract, nasopharynx and oropharynx. This condition is referred to as pseudohemoptysis. *Factitious hemoptysis* is another condition associated with unusual symptoms and a negative evaluation.

A number of diseases have been found to be responsible for alveolar hemorrhage. Although there is no prospective study that has identified the actual reason behind alveolar hemorrhage, yet various studies propose idiopathic pulmonary hemosiderosis, Wegener granulomatosis, microscopic polyangiitis, collagen vascular disease and Goodpasture syndrome as the most common conditions responsible for it.

PATHOPHYSIOLOGY

Pathophysiology is varied just as the causes are. The lung is made up of two vascular systems: (1) the pulmonary system and (2) the bronchial system. Hemoptysis and alveolar hemorrhage can occur in any of these systems. Hemoptysis may be due to various underlying diseases ranging from cardiovascular disease to pulmonary disease. Diseases associated with diffuse alveolar hemorrhage (like idiopathic pulmonary hemosiderosis, Wegener granulomatosis, microscopic polyangiitis, collagen vascular disease, Goodpasture syndrome and pulmonary capillaritis) are likely to have neutrophil infiltration into the alveoli and bronchioles causes breakage of capillaries which further results into infiltration of RBCs in the alveolar region. Recurrent alveolar hemorrhage can further progress to pneumonia, deposition of collagen in the smaller airways, and ultimately to fibrosis or respiratory failure.

CLINICAL FEATURES

The clinical symptoms of alveolar hemorrhage include alveolar bleeding or those related to the underlying cause. The common initial symptoms include dyspnea, cough, and fever often along

Table 1 Common causes of hemoptysis

<i>Respiratory</i>
• Respiratory tract infections—pneumonia, tracheobronchitis, pharyngitis, tuberculosis
• Cystic fibrosis
• Foreign body aspiration
• Nasopharyngeal bleeding
• Bronchiectasis
• Pulmonary neoplasms
• Carcinoma
<i>Others</i>
• Congenital heart disease
• Cysts in lungs
• Unknown causes

with hemoptysis. Sometimes hemoptysis may go unnoticed initially, because the alveoli absorb a large volume of the blood. A careful record helps in differentiating between hemoptysis, pseudohemoptysis, and hematemesis. The most common causes in pediatric patients include: infections of the lower airways and foreign body aspiration, whereas cystic fibrosis and bronchiectasis are secondary causes. Bronchitis, pneumonia and lung carcinoma are the major causes in adults.

DIAGNOSIS

Hemoptysis

Diagnostic approach for hemoptysis consists of following steps:

- Clinical records of the patients for past history of the present symptoms and associated family history.
- Assessment of blood loss consisting of duration, frequency and amount of blood and whether the blood was expelled by coughing or vomiting.
- Sputum sample analysis for confirming hemoptysis.
- Radiographic examination consisting of chest X-ray, high resolution computed tomography (HRCT) scan, bronchial angiography.
- Laboratory testing includes blood tests for WBC analysis and cells morphology in sputum and culture and bacterial identification tests.
- Bronchoscopy and bronchoalveolar lavage (BAL) for hemosiderin-laden macrophages (HLM).

Alveolar Hemorrhage

The diagnosis of alveolar hemorrhage largely depends upon clinical features of underlying disease. The most common clinical features involved are dyspnea, cough, hemoptysis, and new alveolar infiltrates along with blood-stained BAL specimens (containing numerous erythrocytes and siderophages). Unlike bleed from the airway disease like bronchiectasis, these cases often do not have significant cough or sputum production. As the symptoms are not specific in nature, the recognition of alveolar hemorrhage often requires BAL analysis. Gross hemoptysis is absent in up to one-third of patients and they may be identified by detecting blood tinged BAL during interval fiberoptic bronchoscopy. The diagnosis of alveolar hemorrhage is a tedious task as the symptoms are nonspecific nature. A number of factors are taken into consideration while making the final diagnosis, i.e., clinical features, radiographic procedures (HRCT and pulmonary arteriogram) and bronchoalveolar analysis. After the correct diagnosis is established, the underlying cause of the condition must be targeted to initiate the therapeutic process.

MANAGEMENT

Management of alveolar hemorrhage and hemoptysis aims at protecting the airways; and maintaining the structure of the airways, oxygen content and blood volume. Treatment largely depends upon underlying cause of the disease and it should be worked up properly. Cough suppressants can be used for minor hemoptysis, whereas tuberculosis is treated with anti-tubercular therapy. Infections are to be treated appropriately as per etiology.

For the therapy of idiopathic pulmonary hemosiderosis, prednisolone is used with or without hydroxychloroquine. Corticosteroids and immunosuppressive drugs are the therapy of choice and remain the gold standard for the treatment of other conditions with diffuse alveolar hemorrhage like Wegener's granulomatosis. At times when corticosteroids become less effective, other immunosuppressive drugs are used as therapeutic regimens including cyclophosphamide, azathioprine, etanercept

and mycophenolate mofetil. Other protective strategies such as oxygen supplementation, use of bronchodilators and intubation with bronchial tamponade are also used when lung damage is less.

Various techniques are used for the treatment of massive hemoptysis due to bronchial bleed seen with bronchiectasis of varied causes. These include CO₂ laser bronchoscopy, endoscopic tumor excision, vasoconstriction therapy, and lobectomy. In case if hemorrhage continues even after endoscopic measures, then emergency arteriography is done. Severe hemoptysis is managed by bronchial artery embolization (BAE). This technique demands angiographic skills and is a challenging task that is not always available in pediatric settings. Moreover, it is associated with neurological damage due to embolization of spinal arteries.

PROGNOSIS

The prognosis of alveolar hemorrhage and hemoptysis is largely based on the underlying cause of the condition. Repeated incidents of hemorrhage may further cause interstitial fibrosis and respiratory failure. Identification of underlying cause is necessary for proper therapy. Diagnosis of underlying cause plays an important role in the management of massive hemoptysis (> 1,000 mL blood volume within a day). The mortality rate depends upon the underlying condition. Bronchiectasis and bronchitis are at low risk of mortality as compared to patients with tuberculosis and pulmonary carcinoma.

IN A NUTSHELL

1. Alveolar hemorrhage and hemoptysis are the critical conditions. The severity depends upon the associated medical problems.
2. The diagnosis of such conditions at early stage and prior treatment is required to prevent the progressive damage to the airways.
3. There remains a lot of ambiguity on the therapeutic regimens. Further research is needed to reveal the proper treatment modalities.

Chapter 39.27

Primary Ciliary Dyskinesia

Ada Y Yip, Daniel K Ng

Primary ciliary dyskinesia (PCD) refers to primary defect in structure or function of cilia leading to their dysmotility or immobility. Dynein arms defects account for more than 80% of cases. PCD is characterized by chronic upper and lower respiratory tract infection with or without mirror image arrangement. The well-known triad of sinusitis, bronchiectasis and situs inversus is called Kartagener syndrome. Among those with PCD, 48% have situs inversus.

Secondary cilia changes are defects in cilia structure found in up to 3% of ciliated cells of a healthy individual. The percentage would be higher after exposure to pollutant, infection or inflammation. Inner dynein arm and radial spokes defects are commonly seen. They must be differentiated from primary defect by repeating diagnostic test with a new sample that is taken 4–8 weeks later, the turnover time of respiratory epithelium.

EPIDEMIOLOGY

In Europe, prevalence of PCD is 1:15,000–1:30,000 live births, but a wide variation among different European countries has been reported. A cohort study conducted by O'Challaghan et al., has showed that PCD can be as common as 1:2265 in a British Asian in Bradford. PCD is largely inherited in an autosomal recessive manner. Autosomal dominant or X-linked inheritance is also reported.

ETIOLOGY

Primary defect in cilia results in generalized functional impairment of ciliated cells in their propelling functions, resulting in stasis of mucus in the sinuses, middle ear, respiratory tract or impaired movement of sperms or fertilized ovum resulting in sinusitis, otitis media with effusion, bronchiectasis, infertile male and ectopic pregnancy, respectively.

Cilia are complex structure made up of more than 200 polypeptides. The protein size is large and the genetic make-up was diverse. DNAI1 mutation accounts for ~10% of PCD and DNAH5 mutation accounts for ~20% of PCD. Both of them account for 20–40% of PCD patients with outer dynein arm defect. A mutation at DNAI1V5+2_3insT is responsible for more than 50% of mutations. Other mutations like DNAH5, DNAI1, DNAI2 are also associated with outer dynein arm defect. KTU and LRRC50 are associated with combined dynein arm defect. DNAH11 is associated with situs inversus but not dynein arm defect. RPGR is associated with X-linked retinitis pigmentosa and sensory hearing deficits. The above list is not exhaustive and many more genes are yet to be discovered in this genetically heterogeneous disease.

PATHOPHYSIOLOGY

Cilia are organelles that consist of hundreds of polypeptides. Most cilia have a typical 9+2 ultrastructure (**Fig. 1**), i.e., 9 microtubule doublets (microtubule A and B) surrounding a pair of central singlet microtubules. Each of the peripheral doublets is linked to their adjacent pair by nexin links and is connected to the central pair microtubules by radial spokes. Inner and outer dynein arms are ATP-containing units that are located on microtubule A and are responsible for sliding along adjacent microtubule B during movement. Nexin links and radial spokes restrain the degree of sliding and cause cilia to bend. Cilia are classified into motile cilia, nodal cilia and primary cilia.

Figure 1 9+2 ultrastructure of cilia

Motile cilia have 9+2 ultrastructure. They line the surface of nasal cavity, sinuses, middle ear, eustachian tube and tracheobronchial tree. About 200 cilia are found on apical surface of each epithelial cell and they beat synchronously at a natural frequency of 8–20 Hz to form a metachronal wave. Each cilium beat cycle consists of a powerful effective stroke that propels mucus forward and a slow recovery stroke that brings cilium back to its original position along the same plane. Any defect that impairs cilia beat frequency, beat coordination or change in chemophysical nature of mucus (like cystic fibrosis) will result in impaired mucociliary clearance. Mucus pooling predisposes to infection and causes rhinosinusitis, otitis media, glue ear, bronchitis, pneumonia, and bronchiectasis. Motile cilia are also found on ependyma, Fallopian tube and flagella of sperm; defect of which will result in hydrocephalus, ectopic pregnancy and infertility respectively.

Nodal cilia are the only motile cilia found at embryonic stage. They have 9+0 configuration as they lack central microtubules and have a unidirectional rotatory movement that result in leftward flow of extracellular fluid, which is important in signaling left-right orientation. Any defect in nodal cilia function will result in random organization of internal organ, causing left-right laterality problem, found in nearly half of the cases with PCD. This includes situs inversus totalis (48%), situs ambiguus (6%), abdominal organs and pulmonary situs abnormalities.

Primary cilia are immotile cilia with 9+0 ultrastructure and no dynein arms. They are mono-cilia and are found in many organs including eyes, liver, kidney, etc. Some of them have sensory function and act as photoreceptors and olfactory receptors. Defect of primary cilia may result in a wide variety of diseases like tracheoesophageal fistula, severe esophageal reflux, biliary atresia, polycystic kidneys, abnormal leukocyte function, rheumatoid arthritis, etc.

CLINICAL PRESENTATION

Newborns with family history of PCD, persistent rhinitis (76% of PCD), unexplained tachypnea or respiratory distress due to delayed removal of lung fluid after birth (> 75% of PCD) and left-right laterality problem like situs inversus (40–50% of PCD), heterotaxy (6% of PCD), isomerism or dextrocardia warrant an early investigation for PCD. Chronic rhinosinusitis, otitis media, otitis media with effusion (51% of PCD) resulting in conductive hearing loss, chronic wet cough (universal), wheeze, protracted bronchitis and recurrent pneumonia are common clinical features in childhood. Digital clubbing and bronchiectasis are present in 83% of adults with PCD. Half of the affected adult males are infertile due to impaired spermatozoa motility, while adult females

are usually subfertile with an increased risk of ectopic pregnancy because of impaired Fallopian tube transport. Other presentations like hydrocephalus, severe gastroesophageal reflux and biliary atresia are rarely seen.

DIFFERENTIAL DIAGNOSES

Differential diagnoses mainly cover the diagnoses leading to bronchiectasis or persistent bacterial bronchitis. They include immunodeficiencies (congenital or acquired), gastroesophageal reflux with or without aspiration, dysfunctional swallowing, and structural airway lesion like tracheoesophageal fistula.

APPROACH TO DIAGNOSIS

Saccharin Test

Saccharin test has been used for many years as a crude assessment of mucociliary function. It is done by putting a saccharine micro-tablet on the inferior turbinate of an individual who sit-still and inclined forward. No coughing, sniffing or swallowing is allowed. Saccharin is expected to be tasted within 60 minutes. Failure or delay in tasting is suggestive of abnormal ciliary function. This test is limited by the fact that it is unreliable in young children less than 6 years old, hence unable to aid diagnosis in half of the cases as median age for PCD diagnosis is 5.3 years old and cilia with dyskinetic movement will be missed. Few centers now instead look for a migration of a small amount of gel containing radioactive material in the anterior nares to confirm presence or absence of ciliary movements.

Nasal Nitric Oxide Test

Nasal nitric oxide (NO) is produced by nitric oxide synthase mainly from paranasal sinus epithelium. It is present in high concentration in the upper respiratory tract and is believed to have a role in local defense against microbes, cilia motility regulation, effect on bronchial tone and pulmonary vascular resistance. Extremely low (about 10% of normal) nasal NO level is detected in PCD. If nasal NO level is more than 150 ppb, PCD can be excluded with certainty.

Ciliary Studies

A complete assessment of cilia ultrastructure is possible by transmission electron microscope (TEM), assessment of ciliary beat frequency, pattern and coordination of movement. When necessary, cilia should be cultured to get rid of damages secondary to infection and inflammation for analysis. All these testes required a high degree of expertise and should be performed in centers experienced in taking care of patients with PCD.

Electron microscopy Cilia ultrastructure can be assessed by TEM. Most commonly encountered structural defect is outer dynein arm defect (43%), followed by inner dynein arm defect (23%), mixed inner and outer dynein arm defect (18%) and central apparatus defect (1%). Quality of sample is similar at nasal or tracheal level. However, it has to be free from recent infection to avoid secondary changes. Compound cilia and microtubules defects are typical secondary features. Inner dynein arm defect and radial spoke defect are also commonly seen after infective insult. Hence, a mandatory second sampling for analysis has to be performed 4–8 weeks after the last infection to avoid false positives.

Ciliary beat frequency Mucociliary beat frequency (CBF) and pattern (CBP) analysis by high-speed video technology under microscope help to pick up 15% PCD that have normal structure under TEM. Normal cilia beat forward and backward in the same plane without sideway sweep at a frequency of 12–14 Hz, while those with PCD beat at ~3 Hz or slower. Different ultra-structure defect can result in different beat pattern. Cilia with

outer dynein arm defects or mixed defects are virtually immotile with the occasional low-amplitude flickering motion. Those with inner dynein arm defect or radial spoke defects have a stiff beating movement with reduced amplitude and those with transposition defects beat at circular patterns. A normal mucociliary beat frequency and pattern makes PCD unlikely.

Cell culture Cell culture is a demanding and time consuming technique used to eliminate environmental influence on cilia structure and function. It is done by growing ciliated epithelial cells in an antibiotics-containing medium. The newly grown cilia, which are free from any secondary changes, are used for diagnostic tests like TEM, CBF and CBP analysis. Cell culture is mostly used in eliminating false positives due to chronic infection and to confirm less common phenotypes, like ciliary disorientation, ciliary aplasia, central microtubular agenesis and inner dynein arm defects.

MANAGEMENT

The aims of treatment are to prevent and treat pulmonary exacerbation so as to minimize lung damage, to control nonpulmonary symptoms and to promote normal growth and development. The management includes antibiotics, inhaled medications, anti-inflammatory medications, airway clearance, immunizations and fertility advice. Early diagnosis and implementation of a multi-disciplinary approach is associated with better outcome.

General measure including adequate up-to-date vaccination and environmental control to avoid pollutant, including cigarette smoke, should always be implemented. Nutritional support with calorie at 110–120% of that recommended for a normal population is required to support adequate normal growth in those symptomatic PCD.

Pulmonary Control

This is classified according to clinical features (**Table 1**). Pulmonary treatment (**Table 2**) includes measures to improve mucociliary clearance, to minimize lung damage due to infection and to decrease airway inflammation. Daily chest physiotherapy is essential for mucous removal. Exercise is encouraged because both taking deep breath and its bronchodilation effect help in mucous removal. Normotonic or hypertonic saline nebulizer is also helpful to clear sputum in our experience. DNase is useful in cystic fibrosis (CF), but case reports showed conflicting results

Table 1 Classification of control of PCD

Symptoms in the previous week	Controlled	Partly controlled	Uncontrolled
Cough	Little or no	Increased	> 3 features
Sputum volume and color	Little or no sputum	Increased volume or yellowish/greenish color	
Limitation of physical activities	None	Any	
Affect social life/daily activities	None	Any	
Emergency admission for pulmonary exacerbation	None	1 or 2/year	3 or more/year

Table 2 Stepwise approach to treatment of PCD

Basics	Step 1	Step 2	Step 3	Step 4
Aim to maintain lung function, decrease exacerbation and emergency admission Allow normal daily life				
← Step down if improving and step up if deteriorating →				
	5.85% NaCl solution nebulized for 10–15 minutes QD	5.85% NaCl solution nebulized for 10–15 minutes BD	5.85% NaCl solution nebulized for 10–15 minutes TDS	Multidisciplinary meeting to work out a tailor-made regime to arrest the deterioration
Education	Chest physiotherapy QD	Chest physiotherapy BD	Chest physiotherapy TDS	
Environmental control	Breathing exercise with resistor/vibrator, e.g., Acapella QD	Breathing exercise with resistor/vibrator, e.g., Acapella BD	Breathing exercise with resistor/vibrator, e.g., Acapella TDS	
Avoid pollutants exposure	*Bronchodilator (when necessary)	*Bronchodilator (when necessary)	*Trial of LABA + ICS (stop after 3 months if no benefit is demonstrated)	
Aerobic exercise			"Eradication and/or ^long-term cycled therapy with Neb and/or systemic antibiotic	
Immunization			Consider other measures to help airway clearance (i.e., CPAP, cough assist)	
Nutrition		#Antibiotic (2 weeks course)		

*Only in those with documented airway bronchodilator responsiveness.

#Sputum/induced sputum should be performed at least every 3 months, prescribe antibiotic according to latest sensitivity result; start with amoxicillin, if sputum showed commensals only/Co-amoxycyclavulanate, if the patient is at risk of aspiration.

"Eradication therapy for *Pseudomonas*: IV antipseudomonal antibiotics for 2 weeks ± colistin nebulization 75–150 mg (1–2 million units) BD for 2 weeks–3 months.

^ Long-term cycled therapy, usually start with 2–4 weeks of PO and/or Neb antibiotic, to be given every 3 months. Nebulized therapy: Gentamicin 80 mg BD or colistin (depending on bacterial culture and sensitivity).

^3 times per week azithromycin (10 mg/kg/dose) may help to reduce exacerbation and cough.

when used in PCD. Mucolytics are not useful while antitussive medication should be avoided.

Antibiotics Prompt and aggressive treatment of respiratory infection is the key to treatment. High dose oral antibiotics should be started at first sign of acute pulmonary exacerbation and it has been demonstrated to lead to improvement in lung function. Antibiotics choice should be guided by current or previous sputum culture result. If it is not available, oral Co-amoxycyclavulanate can be given empirically based on the fact that *Haemophilus influenzae*, *Staphylococcus aureus*, *Streptococcus pneumoniae* are the most common isolated organisms. Atypical *Mycobacterium* and *Pseudomonas species* tend to affect children of older age. Induced sputum for culture should be saved for surveillance every 3 months during acute exacerbation or when clinical response to treatment is suboptimal. Antibiotics choice should be changed according to sensitivity result. Prophylactic treatment is only considered in those experience recurrent pulmonary exacerbation and those with poor lung function. *Pseudomonas* infection (**Table 3**) should be treated with an aim to eradicate, while long-term antipseudomonal therapy should be given for chronically infected patients.

Anti-inflammatory treatment Case reports have demonstrated beneficial effects of macrolides in PCD. Azithromycin shows a good immunomodulatory effect, antisecretion effect with minimal side effect. Other anti-inflammatory medications like oral steroid and nonsteroidal anti-inflammatory drug are not recommended. Inhaled corticosteroids are not given routinely unless the patient is deteriorating. Clear outcome measures and success criteria need to be decided *a priori* to guide the continuation of inhaled corticosteroids beyond 3–6 months of trial.

Nonpulmonary Treatment

This includes daily nasal lavage with home-made or proprietary saline preparation (**Box 1**) and the authors found the 1.5% NaCl solution delivered by syringe with head-tilted to be highly effective and safe for the 1.5% NaCl solution. High dose antibiotics should be given for acute sinusitis. Acute otitis media should be treated with antibiotics while effusion should be managed conservatively with regular audiometry monitoring. Hearing aid may be considered if necessary, but grommet insertion should be avoided due to persistent otorrhea in 33% cases. Infertility can be managed by technology assisted fertility by intracytoplasmic injection of sperm or *in vitro* fertilization.

PROGNOSTIC FACTORS

Regular lung function monitoring is essential. Chest X-ray is easily accessible, but its sensitivity to early bronchiectasis is low. High resolution computer tomography (HRCT) is superior in this aspect but large radiation dose prohibit it from being used regularly. More than 50% children and 100% adults PCD patients have bronchiectasis. Delayed diagnosis, recurrent and severe infection are indicators for more extensive involvement. Middle and lower lobes of lung are more likely to be affected due to less effective mucus drainage by gravity. One-third of PCD patient have FEV₁ (forced expired volume in one second) less than 80% predicted at diagnosis. Those diagnosed late tends to have poorer lung function. With good adherence to treatment from expert centers for 10 years, 60% PCD patients' FEV₁ remain static, 10% show at least 10% improvement, but ~33% still deteriorate by more than 10%.

Table 3 Treatment for *Pseudomonas* infection

Step 1	First time isolation	Ciprofloxacin PO for 2 weeks
Step 2	Failed eradication with 1st line treatment	IV antipseudomonal antibiotics for 2 weeks OR Ciprofloxacin PO for 4 weeks + Colistin nebulization for 3 months OR Colistin nebulization for 3 months
Step 3	Long-term treatment for colonization	Gentamicin nebulization 80 mg BD OR Tobramycin nebulization 160 mg BD OR Colistin nebulization 1–2 MU BD

Abbreviation: po, per oral.

BOX 1 Methods of performing nasal lavage**Method 1 (Head-tilt)**

1. Tilt head to one side or lie on bed on the side
2. Breathe through the mouth. Avoid nasal breathing, talking or swallowing for the risk of aspiration
3. Push in irrigation fluid via one nostril (via nostril on upper side) and the fluid will exit from the other nostril or through the mouth
4. Repeat Step 3 with head tilted to the other side

Method 1**Method 2****Method 2 (Upright)**

1. Sit down with head up
2. Hold the breath
3. Push in irrigation fluid via one nostril and allow fluid to pass down the throat
4. Lean forward with head down and allow irrigation fluid to drip out from nostrils or split out from throat.

PREVENTION

Antenatal counseling of affected family and genetic investigation, if gene involved is known. Otherwise, there is no effective way to prevent PCD.

IN A NUTSHELL

1. Primary ciliary dyskinesia could be due to structural or functional defects of cilia.
2. Outer and inner dynein arm defect accounted for 80% of cases.
3. Nasal exhaled nitric oxide more than 150 ppb excludes PCD.
4. Rhinosinusitis, otitis media and persistent bacterial bronchitis are commonly found in PCD.
5. Bronchiectasis is identified in more than 50% children and 100% adult with PCD.
6. Around 33% of PCD patients had FEV₁ dropped by more than 10% in 10 years follow-up.
7. Early use of antibiotics for pulmonary exacerbation is essential to preserve lung functions.
8. Regular chest physiotherapy and inhalation of hypertonic saline are important to prevent exacerbation of bronchiectasis.

Chapter 39.28

Cystic Fibrosis

SK Kabra, Kana Ram Jat, Rakesh Lodha

Cystic fibrosis (CF) is the most common life limiting recessive genetic disorder in Caucasians with an incidence of approximately 1 in 2,500 children born in the United Kingdom. It is less common in African Americans (1 in 15,000) and in Asian Americans (1:31,000). It also affects other ethnic groups such as black population with an incidence of 1 in 17,000 and the native American population with an approximate incidence of 1 in 80,000.

EPIDEMIOLOGY

Cystic fibrosis was thought to be extremely rare in India. Recent reviews suggest that CF does occur in Indian children. The incidence in migrant Indian populations in the USA has been estimated to be 1 in 40,000 while in UK it has been estimated 1 in between 10,000 and 12,000. The precise incidence of CF among Indians is unknown. Low level of suspicion and poor availability of facilities for diagnosis have delayed the diagnosis in our country. The median age of diagnosis among Indian Americans is 12 months compared with 6 months among Caucasian American children and reflects a low index of suspicion for the disease even among Indians in western countries. Delayed diagnosis of CF results in severe malnutrition which is one of the bad prognostic indicators for survival.

ETIOPATHOGENESIS

The basic defect in CF is a mutation in the gene for chloride conductance channel, i.e., cystic fibrosis transmembrane conductance regulator (CFTR) located on chromosome 7. The failure of chloride conductance by epithelial cells leads to dehydration of secretions that are too viscid and difficult to clear.

Till now more than 1,800 mutations in the gene have been recognized (www.genet.sickkids.on.ca). The most common mutation is delta F 508 which constitutes about 70% of the total cases. The frequency of this mutation in Indian children is reported to be between 19% and 44%. The proportion of children with delta F 508 mutations from other countries in Asia is less than that in the Caucasian population.

CLINICAL FEATURES

The clinical features of CF are variable and depend on age of diagnosis, supportive care and treatment received. The common clinical presentation includes meconium ileus in neonatal period, recurrent bronchiolitis in infancy and early childhood, recurrent lower respiratory tract infections, chronic lung disease, bronchiectasis, steatorrhea and with increasing age pancreatitis and azoospermia. Pancreatic insufficiency is present in more than 85% of CF patients (**Table 1**).

DIAGNOSIS

The diagnosis of CF should be suspected by the presence of a typical phenotype or family history and confirmed by the demonstration of a high sweat chloride (> 60 mEq/L) on two occasions and/or by identifying CF causing mutations on both the alleles of the child. Nasal potential difference measurements can be used as an alternative to sweat test but is not widely available.

In the absence of sweat chloride estimation and mutation analysis at most centers in India, CF may be suspected on presence of supportive investigations as given in **Flow chart 1**. Children with

Table 1 Common clinical features of cystic fibrosis

0–2 years	%
Steatorrhea	85
Failure to thrive	85
Rectal prolapse	20
Meconium ileus	10–15
Obstructive jaundice	15–20
Hypoproteinemia/anemia	15–20
Bleeding diathesis	15–20
Heat prostration /hyponatremia	15–20
Bronchitis/bronchiolitis	15–20
Staphylococcal pneumonia	15–20
2–12 years	
Malabsorption	85
Recurrent pneumonia	60
Nasal polyposis	6–36
Intussusception	1–5
> 12 years	
Clubbing	
Azoospermia	98
Chronic pulmonary disease	70

Abnormal GTT	20–30
Focal biliary cirrhosis	10–20
Gallstones	4–14
Diabetes mellitus	7

suspected CF may be treated with supportive care, but label of CF should be given after confirmation by sweat test or mutations.

DIFFERENTIAL DIAGNOSIS

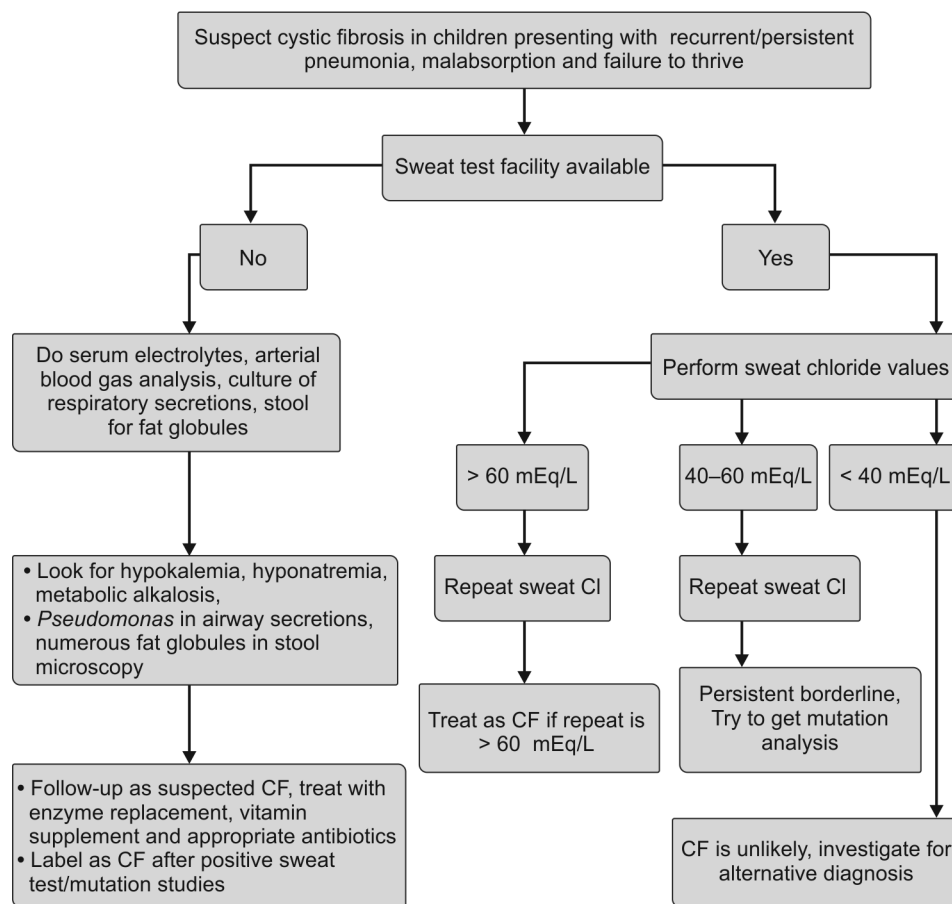

Children presenting with recurrent pneumonia and gastrointestinal infections (diarrhea) secondary to primary or secondary immune deficiency may closely mimic CF. Children with CF may have frequency of stool, that is large volume, foul smelling and greasy, while infective diarrhea produces watery or blood stained stools. Children with immune deficiency may have multisite recurrent infections due to usual as well as unusual microbial agents, while children with CF get predominantly GI and respiratory symptoms.

MANAGEMENT

The treatment of CF in children includes respiratory management; nutritional care; anticipation and early diagnosis of liver disease, diabetes and other organ dysfunction.

Respiratory Management

Lung damage in CF is caused by excessive poorly effective inflammatory processes in response to bacterial infection of normally sterile airways. Respiratory therapy aims to limit lung damage by decreasing the number of infecting organisms and suppressing the inflammatory process and hyper-reactivity of airways. The principle components of care used to achieve this include (a) airway clearance techniques, (b) antibiotics, and (c) anti-inflammatory agents.

Flow chart 1 Approach to diagnosis and management of cystic fibrosis

Airway Clearance Techniques

The airway secretions are viscid in CF. These are difficult to clear and lead to secondary infections and damage to respiratory tract. Airways can be kept clear by adequate hydration, chest physiotherapy, and judicious use of antibiotics and mucolytic agents. To keep the secretions less viscid, it is important to maintain good hydration by ensuring intake of plenty of liquids and extra salt.

Chest Physiotherapy

Chest physiotherapy techniques for keeping airways clean includes following methods: (i) Postural drainage and chest clapping; (ii) active cycles of breathing; (iii) positive expiratory pressures (PEP); (iv) high pressure PEP; (v) flutter therapy; (vi) autogenic drainage; and (vii) high frequency chest wall oscillation (HFCWO). The method can be selected for an individual on the basis of age of the patient, clinical status, experience of the physiotherapist, personal preference of patients, and social issues including level of support. For infants and young children, postural drainage and chest clapping may be more convenient. Cyclical breathing and autogenic drainage require patient's cooperation and can be used in older children. Flutter therapy, PEP, and HFCWO require special devices and training. They can be used under supervision of the physiotherapist.

Mucolytic Agents

Various mucolytic agents have been used by oral as well as inhalation route. N-acetylcysteine has propensity to cause bronchospasm, hemorrhagic tracheitis and impaired ciliary clearance, its use is limited to selected cases where other measures

fail to clear the air passage. Recombinant human DNase (rhDNase) has been found to reduce the viscoelasticity and adhesiveness of sputum in animal models. DNase, given as aerosol, increases mucociliary clearance and reduces incidence of respiratory infections; it also decreases rate of hospitalization, number of days missed from work or school and the frequency of CF related symptoms. The side effects of rhDNase are few and mild and include upper airway irritation (voice change, laryngitis, pharyngitis), rash, chest pain, and conjunctivitis. A small proportion of patients (2–4%) may develop antibodies to rhDNase. It is recommended in doses of 2.5 mg once or twice a day. But it is a rather expensive treatment with limited utility. There is no role of oral mucolytic drugs including bromhexine and ambroxol.

Antibiotic Therapy

The commonly encountered microbial agents causing pulmonary exacerbation in children with CF include *Staphylococcus aureus*, *Haemophilus influenzae b*, *Pseudomonas spp*, *Burkholderia cepacia*, etc. Different viruses, *Mycoplasma*, *Mycobacterium spp*, and *Aspergillus* are other important pathogens responsible for pulmonary exacerbation. It is important to select an antibiotic on basis of organisms isolated from respiratory secretions. Periodic cough swab cultures may help in empirical treatment of acute exacerbation.

The drugs effective against common pathogens and their doses are given in **Tables 2 and 3**. The duration of intravenous therapy is 2–4 weeks. An early identification of respiratory infection and administration of oral antibiotics may decrease the need for hospitalization and intravenous antibiotics. The early

Table 2 Organisms associated with exacerbation of pulmonary infection in patients with cystic fibrosis and appropriate intravenous antibiotic treatment

Prevalent bacteria	First choice		Alternative choice	
	Antibiotics	Dose	Antibiotics	Dose
<i>S. aureus</i>	Cefazolin	25–50 mg/kg every 6 hours	Vancomycin	15 mg/kg every 6 hours
<i>H. influenzae</i> and <i>S. aureus</i>	Ticarcillin clavulanate plus Gentamicin	100 mg of ticarcillin per kg and 3.3 mg of clavulanate/kg every 6 hours 3 mg/kg every 8 hours		
<i>S. aureus</i> and <i>P. aeruginosa</i>	Ticarcillin clavulanate Tobramycin plus gentamicin/amikacin	100 mg of ticarcillin per kg and 3.3 mg of clavulanate/kg every 6 hours 3 mg every 8 hours		
<i>P. aeruginosa</i> only	Ticarcillin plus tobramycin	100 mg/kg every 6 hours 15 mg/kg every 12 hours	Tobramycin plus ceftazidime, piperacillin or imipenem Aztreonam plus amikacin	3 mg/kg every 8 hours 50 mg/kg every 8 hours 100 mg/kg every 6 hours 15–25 mg/kg every 8 hours 50 mg/kg every 8 hours 5–7.5 mg/kg every 8 hours
<i>P. aeruginosa</i> and <i>Burkholderia cepacia</i>	Ceftazidime plus ciprofloxacin	50–75 mg/kg every 8 hours 15 mg/kg every 12 hours	Ceftazidime, plus Chloramphenicol or Trimethoprim – sulfamethoxazole	50–75 mg/kg every 8 hours 15–20 mg/kg every 8 hours 5 mg of trimethoprim/kg IV and 25 mg of sulfamethoxazole/kg every 6 hours
<i>B. cepacia</i> only	Chloramphenicol or Trimethoprim sulfamethoxazole or both	15–20 mg/kg every 6 hours 5 mg of trimethoprim/kg and 25 mg of sulfamethoxazole/kg every 6 hours		

Table 3 Oral antibiotics commonly used to suppress respiratory pathogens in patients with cystic fibrosis

Pathogen	Antibiotics	Doses
<i>S. aureus</i>	Cloxacillin	12.5 mg/kg every 6 hours
	Cephalexin	12.5 mg/kg every 6 hours
	Amoxicillin-clavulanate	10–15 mg of amoxicillin/kg and 2.5–3.75 mg of clavulanate/kg every 8 hours
	Erythromycin	15 mg/kg every 8 hours
	Clarithromycin	7.5 mg/kg every 12 hours
<i>H. influenzae</i>	Cefaclor	10–15 mg/kg every 8 hours
	Amoxicillin	10–20 mg/kg every 8 hours
<i>S. aureus</i> and <i>H. influenzae</i>	Cefixime	10 mg/kg/day
	Amoxicillin-clavulanate	10–15 mg of amoxicillin/kg and 2.5–3.75 mg of clavulanate/kg every 8 hours
	Trimethoprim – sulfamethoxazole	5 mg of trimethoprim/kg and 25 mg of sulfamethoxazole/kg every 12 hours
	Cefpodoxime	5 mg/kg every 12 hours
	Cefuroxime	20 mg/kg every 12 hours
<i>P. aeruginosa</i>	Ciprofloxacin	20–30 mg/kg/day in 2–3 divided doses
<i>B. cepacia</i>	Trimethoprim – sulfamethoxazole	5 mg of trimethoprim/kg and 25 mg of sulfamethoxazole/kg every 12 hours

indications of starting oral antibiotics include increase cough and expectoration, change in the color of expectoration, decrease in activity, impaired appetite, fever, and weight loss. Fever may not be a common clinical manifestation of acute exacerbation of infections. The treatment of acute exacerbation of infection, if the patient is known to be colonized with *Pseudomonas* includes

antibiotics effective against *Pseudomonas* (fluoroquinolones, ceftazidime, cefoperazone, piperacillin, imipenem or meropenem in combination with an aminoglycoside). If the colonization status is not known, then a combination of drugs effective against *Pseudomonas* and *Staphylococcus* are used empirically. The commonly used oral antibiotics include fluoroquinolones. These drugs may be started early and given for 2–3 weeks when acute exacerbation is suspected.

Aerosolized antibiotics The airways of CF patients get colonized with *Pseudomonas spp.* and may be responsible for frequent exacerbation. Complete eradication of *Pseudomonas* from airways of CF patient is extremely difficult. Use of aerosolized antibacterials has shown good results in treating patients who are chronically colonized with *Pseudomonas*. The drugs commonly used are tobramycin and colistin. These drugs can be given either daily or intermittent (one month alternating with 1 month off) till 1–2 cough swab cultures are negative for *Pseudomonas*. These can be started again when cultures are positive for *Pseudomonas*.

Bronchodilator and Inhalation Steroid Therapy

Bronchial hyper-responsiveness occurs in 25–50% patients particularly during intercurrent infections and in those with poor baseline lung function. Some patient may have atopic asthma as well as CF. Factors associated with atopic asthma include: exercise induced wheezing, persistent nocturnal coughing, cough or wheeze following exposure to allergens, concomitant eczema and/or rhinitis, and family history of asthma. These patients may benefit with bronchodilators and inhaled steroids and these may be used on a prolonged basis if there is a consistent response to these drugs.

Nutritional Management

Increase Caloric Intake

Many parents may restrict fat intake in diet of children with CF and it may improve their symptoms of malabsorption but at the cost of

poor growth. Parents should be encouraged to give balanced diet without restricting fat. The caloric need increases in situations with persistent chest infection or frequent pulmonary exacerbations. Caloric demand may increase up to 50% during acute pulmonary exacerbation.

Oral Caloric Supplements

In addition to caloric needs, supplementary feeds by using commercial preparations or home made feeds can be used. The caloric supplements are given in addition to the regular meals. For Indian children, caloric supplements can be given by using locally available food.

In some patients, short-term/long-term nasogastric or gastrostomy feeding is required. Indications for nasogastric feeding are (1) no weight gain for 6 months even with adequate caloric intake, (2) acute pulmonary exacerbation with poor oral intake, (3) consistently poor appetite and inability to maintain caloric intake, (4) before major surgical procedures, (5) during periods of increased caloric requirement, e.g., puberty and pregnancy.

The feeds may be home made liquid feeds or commercially available formulae. Pancreatic enzymes should always be given with supplementary feeds.

Supplementation of Fat-soluble Vitamins and Minerals

Children with pancreatic insufficiency are at risk of developing deficiency of fat-soluble vitamins. Recommended doses of vitamin A and D are given in **Table 4**. Recommended doses of vitamin E are 50 mg for children below 1 year of age, 100 mg for children between 1 year and 10 years and 200 mg thereafter. In children with clinical manifestation of vitamin K deficiency and those having liver disease, a dose of 10 mg vitamin K daily is recommended. All vitamins should be given with meals and enzyme. Deficiency of water-soluble vitamins is not common. Role of iron, zinc, and selenium supplements remains uncertain.

Salt loss in sweat is excessive in CF patients. Increased sweating in hot weather may result in clinical manifestations of hyponatremia. Sodium supplement is recommended in hot climate. There are no studies on the doses of daily salt for Indian children. Till data are available, we advise daily extra salt intake of 2.5 g in children below 10 kg, and 5 g in children above 10 kg weight.

Pancreatic Enzyme Supplement

Regular enzyme supplement in form of enteric-coated spherules has improved nutritional management significantly. The enzyme preparation is given with meals. The pancreatic supplements can be given in form of capsules or the spherules can be spread over small amount of food in a teaspoon. It is given just before food. The initial doses of enzyme can be 3,000 (1/3rd capsule)–10,000 IU (one capsule) per meal. Doses can be adjusted by observing stool consistency and weight gain in the child. The enzyme doses can be adjusted with monitoring of frequency and characteristics of stools, and weight gain. The enzyme dose should not exceed 10,000 IU of lipase/kg/day.

Table 4 Recommended doses of vitamin A and D in cystic fibrosis

Age	Recommended daily dose	
	Vitamin A	Vitamin D
Less than 6 weeks	2000 IU	200 IU
6 weeks to 6 months	4000 IU	400 IU
More than 6 months	8000 IU	800 IU

Management of GIT Manifestations

The common GI manifestations in CF include pain in abdomen, abdominal distention, meconium ileus equivalent, intussusception, and meconium peritonitis. Pain abdomen in CF may be due to pancreatic insufficiency, rectal prolapse, gastroesophageal reflux, or intestinal obstruction. Pain, abdominal distention, and rectal prolapse due to pancreatic insufficiency respond to increased doses of enzymes. For gastroesophageal reflux, prokinetic agents along with H-2 receptor antagonist are required. Pain in abdomen secondary to constipation can be treated with oral lactulose in doses of 1 mL/kg/day in two divided doses.

Management of meconium ileus during neonatal period and meconium ileus equivalent includes maintenance of fluid and electrolyte balance, administration of hyperosmolar solutions (Gastrografin) per orally or by enema and bowel washes in some patients. Meconium peritonitis and unresponsive meconium ileus may need surgical intervention.

Management of liver disease Ursodeoxycholic acid may prove to affect the natural history of cystic fibrosis-related liver disease. A regular monitoring of liver function test and imaging studies should be part of management.

Assessment and Monitoring

The assessment of illness and monitoring for progress of illness can be done by clinical examination and various laboratory tests. The assessment may be annual or continuous.

Various clinical scoring systems have been developed to provide both a numerical assessment of patient's status and a way of documenting progress in response to treatment.

Other monitoring include pulmonary function test, X-ray film of chest, chest CT scan, ultrasound abdomen, echocardiography, blood chemistry such as glucose, calcium, vitamin levels, transaminases levels, etc. Frequency of these tests depends on the severity of illness and age of patients.

Gene Therapy

Cystic fibrosis is caused by mutations of the cystic fibrosis transmembrane conductance regulator (*CFTR*) gene. Consequent to mutations in parental genes; airway epithelial cells have insufficient *CFTR* functions. As this can be corrected *in vitro* by transfer of the normal *CFTR* gene into airway epithelial cells, it is reasonable to hypothesize that the respiratory manifestations of CF could be prevented by transfer of the normal *CFTR* cDNA to airway epithelium *in vivo*. Studies on gene therapy have not yet produced any breakthrough.

CFTR Modulators

Research in biochemical manipulation to improve *CFTR* function is of great interest. In this direction, a great success has been documented with the use of medication ivacaftor (Kalydeco), that is a *CFTR* potentiator, and has improved *CFTR* function in patients with the G551D mutation, which represents about 4% of patients with CF. The medication is approved for use in children above 6 years of age with this mutation.

PROGNOSIS

The median life expectancy for CF is now over 30 years, and it is projected that in newborn infants it will become more than 40 years. There is increasing evidence of the advantages of newborn screening for CF and subsequent specialist care in high burden countries and races. Management concentrates on optimizing nutritional status and preventing lung infection and inflammation. Survival analysis of Indian children with CF suggest that early mortality was associated with early onset (below 2 months) of

symptoms, severe malnutrition at the time of diagnosis, more than four episodes of pulmonary exacerbations in a year and colonization with *Pseudomonas*.

IN A NUTSHELL

1. Cystic fibrosis (CF) is an emerging disease in Indian children.
2. CF is autosomal recessively inherited illness. Gene is located on chromosome 7.
3. It is a multisystem illness, predominantly involving respiratory and GI systems during childhood.
4. Diagnosis is based on demonstration of sweat chloride value of more than 60 mEq/L with clinical symptoms.
5. Management consists of airway clearance, antibiotics for pulmonary exacerbations and pancreatic enzyme supplementation.

Chapter 39.29

Bronchiectasis

Lokesh Guglani

Bronchiectasis is a suppurative obstructive lung disorder characterized by thickening and dilatation of bronchial walls leading to persistent airway inflammation and mucus retention, and recurrent pulmonary infectious exacerbations; caused by a variety of pulmonary and systemic disorders. It is usually the end result of chronic obstruction and inflammation in the airways, and leads to persistent symptoms, reduced lung function and progressive damage to the lungs over time. Cystic fibrosis (CF) remains the most common cause of bronchiectasis among children in Europe, America and Australia, and has been discussed separately in Chapter 39.28. Primary ciliary dyskinesia (PCD) has been covered separately in Chapter 39.27. All causes other than CF are combined under the heading *non-CF bronchiectasis* and their assessment and management will be discussed in this chapter.

EPIDEMIOLOGY

Since the first description of suppurative phlegm in patients with bronchiectasis by René Laënnec (the inventor of the stethoscope) in early 19th century, the epidemiology of this condition has changed significantly. The introduction and widespread use of antibiotics and vaccines (specifically for pertussis and measles) throughout 20th century had a significant impact on its prevalence across all age groups. However, it is now being diagnosed relatively early in both developed and developing worlds, primarily due to increasing use of high resolution chest computed tomography (CT) scans. The natural history of bronchiectasis in children and its rate of progression over time are determined by the underlying cause, the extent of lung involvement, and the adherence to prescribed treatments. There are no data regarding cause-specific mortality rates in children, although the outcomes are better defined for CF bronchiectasis.

ETIOLOGY

The various conditions that are known to cause non-CF bronchiectasis are listed in **Box 1**.

PATHOGENESIS

Cole's vicious cycle model explains the pathogenesis of bronchiectasis over time (**Fig. 1**). In the setting of any of the underlying risk factors, the presence of neutrophilic inflammation releases proteases that cause damage to the elastic tissue and smooth muscles in the walls of the airways over time. These alterations of the airway anatomy cause thickening and dilatation of the distal bronchi and bronchioles, leading to retention of mucus and poor clearance of airway secretions. This microenvironment of inflamed respiratory epithelium and excessive mucus allows bacterial proliferation, which over time leads to the colonization of airways with various pathogens. A wide variety of pathogens such as *Staphylococcus*, *Streptococcus*, *Pneumococcus*, *Haemophilus influenzae*, various anaerobic, and microaerophilic bacteria and *Pseudomonas aeruginosa* can be found in the bronchiectatic airways. With repeated infectious exacerbations over time, the damage to the airway walls becomes more extensive, leading to further impairment of mucus clearance, thus perpetuating the vicious cycle of infection → inflammation → mucus retention → infection, over and over again.

Reid categorized the pathologic changes in the airways into cylindrical, saccular/cystic and varicose bronchiectasis (**Table 1**)

BOX 1 Causes of non-CF bronchiectasis in children

1. **Airway Injury:** Tuberculosis, recurrent pneumonia, chronic aspiration, bronchiolitis obliterans (postinfectious or post-transplant), nontuberculous mycobacterial infections
2. **Airway obstruction or anomalies:**
 - **Extrinsic compression:** Vascular ring, tumors, lymphadenopathy
 - **Intraluminal obstruction:** Foreign body impaction, granulation tissue, endobronchial masses (carcinoid, broncholithiasis)
 - **Airway stenosis or malacia**
 - **Airway cartilage/connective tissue disorders:** Mounier-Kuhn syndrome (congenital tracheobronchomegaly), Williams-Campbell syndrome (cartilage deficiency), Marfan syndrome
3. **Impaired airway clearance:** PCD, cystic fibrosis, poor airway clearance secondary to neuromuscular disorders
4. **Immunologic abnormalities:**
 - **Primary immune deficiencies:** Immunoglobulin deficiency, Job syndrome
 - **Acquired immune deficiencies:** HIV infection, post-transplant immunosuppression
5. **Chronic inflammatory disorders:** Inflammatory bowel disease (Crohn disease, ulcerative colitis), autoimmune disorders (rheumatoid arthritis, Sjögren syndrome), allergic bronchopulmonary aspergillosis
6. **Miscellaneous:** Graft-versus-host disease, $\alpha 1$ -antitrypsin deficiency, yellow nail syndrome, Young's syndrome, postradiation fibrosis
7. **Idiopathic.**

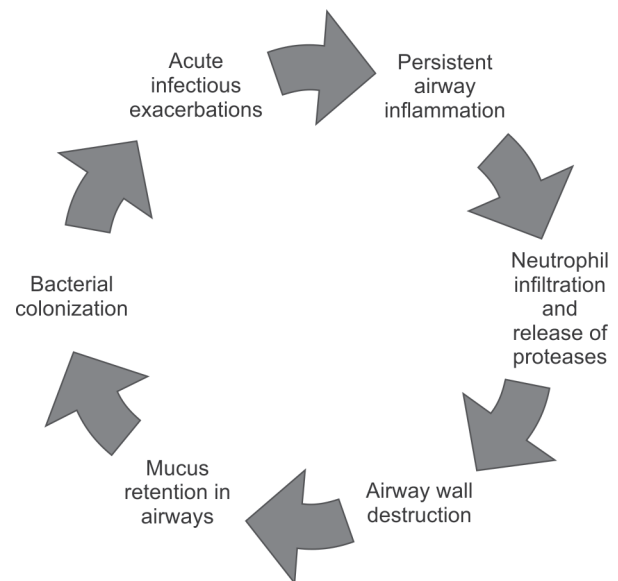

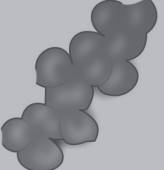

Figure 1 Cole's vicious cycle model to explain the pathogenesis of bronchiectasis

based on the lung histopathologic findings. *Tubular or cylindrical bronchiectasis* represents dilated airways that can sometimes also be seen in patients with pneumonia, but may show some improvement over time. *Saccular or cystic bronchiectasis* occurs with further worsening dilatation of the airways that shows airway segments with large cystic dilatations or saccules, sometimes giving the appearance of a cluster of grapes. *Varicose bronchiectasis* has (just like varicose veins) focal areas of constrictions along a dilated airway that may be due to defects in the bronchial wall.

The initial origin of bronchiectasis can be either focal obstruction (either due to extrinsic compression or intraluminal mass/lesion) involving a specific region or lobe of the lung; or it may be diffuse, in relation to a chronic sinopulmonary condition

Table 1 Pathologic changes in the airways of subjects with bronchiectasis

Categories	Airway changes
	 <p>Normal</p>
Cylindrical	 <p>Cylindrical</p> <p>Dilated bronchi with well defined, straight outlines (tram track appearance, signet ring appearance)</p>
Saccular or cystic	 <p>Cystic</p> <p>Bronchial segments with ballooned appearance (sometimes showing air fluid levels), can appear as clusters of large thick walled cysts (honeycombing)</p>
Varicose	 <p>Varicose</p> <p>Bronchi with alternating areas of dilatation and constriction, giving it a beaded appearance</p>

(such as PCD). The impairment of mucociliary clearance combined with increased mucus production (secondary to hypertrophy of submucosal glands, and metaplasia of goblet cells down into the bronchioles) leads to mucus build up, chronic wet cough, and bacterial colonization. Neutrophils predominate in the airway walls and release proteases and other inflammatory cytokines that cause continued airway inflammation and perpetuation of the vicious cycle of obstruction → infection → inflammation.

CLINICAL FEATURES

Most children with bronchiectasis have a history of persistent, wet cough that may be associated with expectoration of purulent sputum in older children. They may also present with an infectious exacerbation that may sometimes be triggered by a viral infection, with fever, increased cough chest pain and shortness of breath. Presence of chronic sinusitis may indicate ciliary dysfunction, cystic fibrosis or primary immunodeficiency. It is also important to evaluate patients for ongoing aspiration, especially if they have underlying neurologic conditions or congenital anomalies. Presence of an airway foreign body can also lead to repeated infections leading to the development of bronchiectasis over time. Children with bronchiectasis may have increased anteroposterior diameter of the chest due to air trapping as a result of coexistent small airway disease, and may also show digital clubbing. Lung auscultation may reveal localized crackles or rhonchi over the area of involvement in most cases, but wheezing tends to be less common. In general, the progression of bronchiectasis over time may cause patients to develop exercise intolerance and shortness of breath with activity. They may also develop significant failure to thrive and may have chronic hypoxemia requiring supplemental oxygen as their lung involvement becomes more extensive. Hemoptysis may occur due

to erosion of the inflamed airway walls that are in close proximity with pulmonary vessels, but is generally less common in children.

DIFFERENTIAL DIAGNOSIS

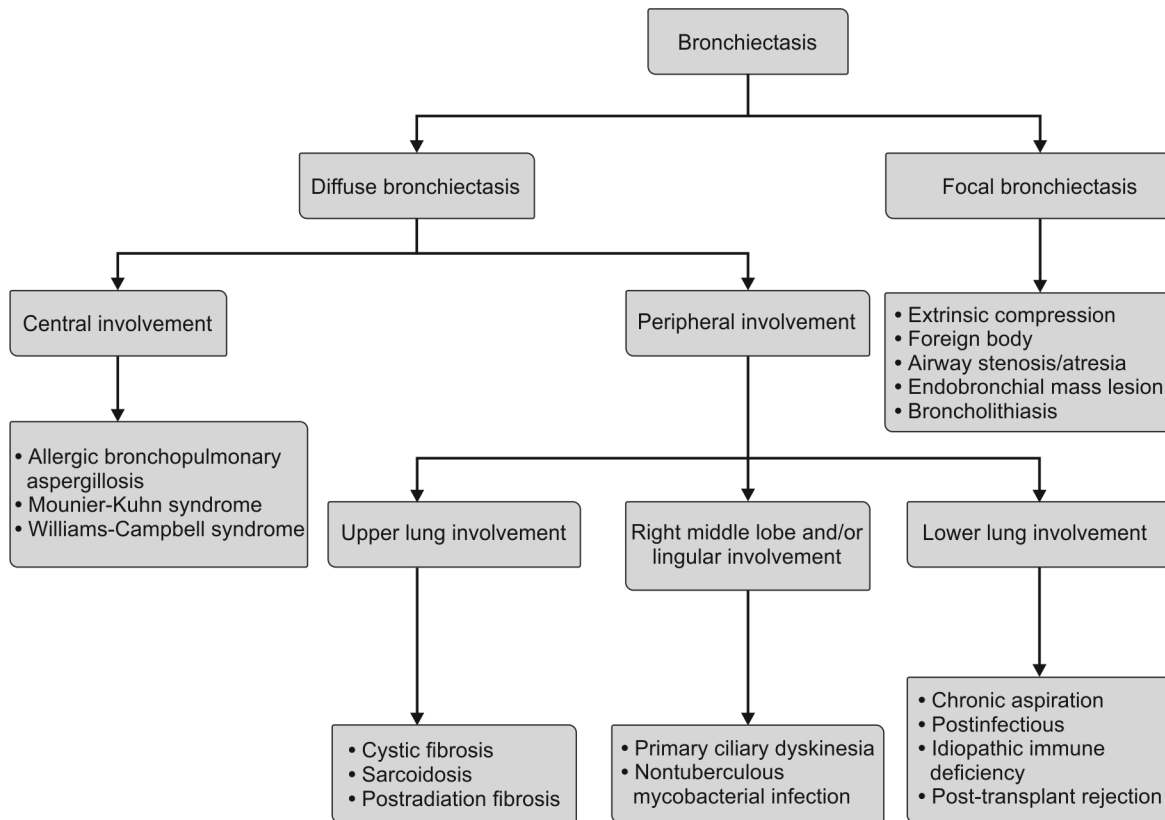

Bronchiectasis should be clinically suspected in children with history of recurrent pneumonias, failure to thrive or chronic wet cough. Since it is a pathologic diagnosis, the underlying cause can be narrowed down from the list of causes in **Box 1**, based on each individual patient's profile and to some extent from the location of the bronchiectatic changes on imaging. **Flow chart 1** shows the patterns of involvement seen on chest CT scan and the associated causes/conditions that are commonly encountered.

Approach to Diagnosis

The diagnostic work-up is directed toward confirming the diagnosis of bronchiectasis, assessing its severity and finally, to confirm its etiology in order to help initiate appropriate therapies. Prior history of specific infections such as tuberculosis or whooping cough in early childhood may lead to postinfectious bronchiectasis. The initial evaluation with a chest X-ray can show dilated thickened airway walls (seen as tram-track lines or ring-shaped shadows for end-on bronchi) but some milder cases may be missed. Other additional abnormalities such as dilated trachea (Mounier-Kuhn syndrome) or persistent atelectasis in one lobe (foreign body or airway compression/mass) may require further testing.

High resolution chest CT is more sensitive as it takes images through 1–1.5 mm slices for every 10 mm of the lung and can better define the extent of lung involvement in bronchiectasis. Airway dilatation can be assessed more objectively, if the airway diameter is noted to be 1.5 times greater than the diameter of the accompanying blood vessel (the *signet ring sign*). Other features such as lack of tapering of the dilated airways as they extend into the periphery of the lung; thickened bronchial walls with extensive mucus plugging; and significant air trapping are additional findings. Localized areas of dilatation of multiple airways within a single lobe can sometimes give the appearance of cystic bronchiectasis. Attention should be paid to other structures such as hilar or mediastinal lymph nodes, vascular anatomy, or congenital airway abnormalities. If the dilated airways can be seen extending up to 1 cm under the pleural surface, it suggests significant dilatation. Some of these early changes (especially those seen in cylindrical bronchiectasis) may be seen in patients with pneumonia and may be reversible after appropriate therapy. Hence, CT imaging should preferably be done after the patient has fully recovered from recent illness.

Initial laboratory evaluation for patients with bronchiectasis should include respiratory cultures to identify specific pathogens (for bacterial, tuberculosis or nontuberculosis mycobacteria and fungal etiologies); tuberculin skin test; sweat test to rule out cystic fibrosis; and basic immunologic work-up (quantitative immunoglobulin levels, antibody responses to diphtheria/tetanus and pneumococcal serotypes). Additional testing may be indicated for patients with suspected chronic aspiration that may be undertaken with modified barium swallow study, videofluoroscopic swallow study, or nuclear scintigraphy. For patients with localized abnormalities on imaging or those who are unable to expectorate sputum, a flexible fiberoptic bronchoscopy should be performed to assess airway anatomy, rule out localized airways obstruction (foreign body, airway anomalies, intraluminal mass lesions or extrinsic airway compression) and to obtain a bronchoalveolar lavage specimen for cultures. A nasal ciliary biopsy may be performed for patients with situs inversus, recurrent sinusitis or otitis media to evaluate for PCD. It is important to remember that the classic triad of Kartagener syndrome (situs inversus, chronic sinusitis and bronchiectasis) is seen in 50% of

Flow chart 1 Patterns of involvement of various etiologies in bronchiectasis

PCD patients. Pulmonary function testing should be performed to assess lung function at baseline, to track response to therapy and monitor changes in lung function over time. Generally, patients with bronchiectasis show an obstructive pattern with low Forced Expiratory Volume in one second (FEV_1) and/or FEV_1 /Force Vital Capacity (FVC) ratio, but some patients with more advanced lung disease may show a mixed obstructive and restrictive defect (latter primarily due to fibrotic changes). For patients with specific features, genetic testing for conditions such as Cystic Fibrosis (steatorrhea, failure to thrive) or PCD (situs in versus, recurrent sinusitis or otitis media) may be considered, if initial screening tests (sweat test or nasal ciliary biopsy) are positive or equivocal.

MANAGEMENT

Once bronchiectasis has been diagnosed, therapies are initiated to prevent further progression of damage to the airway walls, to control symptoms and minimize infectious exacerbations. The long-term management of bronchiectasis includes the following components:

- Airway clearance techniques to aid the removal of excessive airway secretions
- Inhaled mucolytics to enhance the removal of secretions
- Antibiotics
- Anti-inflammatory medications
- Immunization and general protective strategies.

Airway Clearance Techniques

Airway clearance therapies can be individualized based on patient's age, preference and availability of equipment. Manual chest percussive therapy with cupped hands for younger patients or huff-cough techniques for older patients can help to mobilize the secretions. Use of handheld devices such as Acapella, Flutter, Lung

Flute or Quake is based on their ability to transmit vibrations down the airways and loosen up the secretions. High frequency chest wall oscillation device (or Chest Vest) has been used in CF patients, but can also be useful for patients with non-CF bronchiectasis.

Inhaled Mucolytics

Inhaled mucolytic medications such as 7.2% hypertonic saline have been used. Use of recombinant human DNase (Pulmozyme®) has not been shown to be effective for patients with non-CF bronchiectasis. Use of inhaled bronchodilators may be helpful for patients with significant airway reactivity.

Antibiotics

Antibiotic therapy for acute exacerbations can be determined based on the pattern of airway colonization for each patient. Sputum may be difficult to obtain in younger children, but induced sputum techniques or use of throat swabs from posterior pharynx can be useful in guiding antibiotic selection. Even without culture results, treatment can be started (with amoxicillin-clavulanic acid, or with second or third generation cephalosporins) to cover the most common pathogens seen in the airways of patients with bronchiectasis. For outpatient therapy, these antibiotics should be prescribed for at least 10–14 days, but if there is failure to respond to oral antibiotics or a severe acute illness, then intravenous antibiotics may become necessary. As the airways of patients with bronchiectasis become colonized with specific pathogens over time, they may require chronic therapy to prevent acute exacerbations or further worsening of lung function. Like CF patients, many non-CF bronchiectasis patients also get colonized with *Pseudomonas aeruginosa* and may benefit from long-term use of inhaled antibiotics (inhaled tobramycin, aztreonam) to suppress the growth of *Pseudomonas* in their airways.

Anti-inflammatory Drugs

Anti-inflammatory therapies that have been utilized in patients with bronchiectasis include oral azithromycin (administered 3 times a week) and high-dose ibuprofen. Data for their effectiveness is mostly extrapolated from CF literature, and there are no direct studies in children with non-CF bronchiectasis. Inhaled corticosteroids may have a limited role as anti-inflammatory agents in non-CF bronchiectasis, and should be prescribed if a patient has comorbid reversible bronchospasm as well.

Supportive Management

Finally, adequate immunization should be ensured for all children with bronchiectasis and they should continue to receive yearly influenza vaccination. Children above 24 months of age should also receive a booster dose of 23-valent pneumococcal vaccine to keep them protected against pneumococcal pneumonias. Those with underlying immune deficiency should not be given live viral vaccines.

Prevention of exposure to cigarette smoke and other inhaled irritants, avoiding contact with individuals with a cold or respiratory infection, and adequate nutritional rehabilitation are general preventive strategies that can help to improve the quality of life of patients with non-CF bronchiectasis. A specialist should periodically evaluate children with non-CF bronchiectasis and if possible, their lung function and nutritional status should be tracked over time to monitor response to therapies and to assess the natural history of their disease. Oxygen supplementation may become necessary for patients with more advanced disease once they develop chronic hypoxemia due to severe ventilation-perfusion mismatch. Surgical resection of involved lung lobes may be considered for patients with focal bronchiectasis, especially if they continue to have failure to thrive, severe infections, or recurrent hemoptysis despite optimal medical therapies. Patients with diffuse lung involvement, whose bronchiectasis has progressed to severe end-stage lung disease ($FEV_1 < 15\%$), may require bilateral lung transplantation as a last resort treatment option.

PROGNOSIS

The outcomes for patients with non-CF bronchiectasis generally depend on the nature of the underlying disease process, the age of onset, the rapidity of progression of airway wall changes and patient's adherence to prescribed therapies.

PREVENTION

Prompt evaluation of chronic wet cough, treatment of respiratory infections with appropriate antibiotics, nutritional rehabilitation,

and provision of adequate immunization coverage can be helpful in preventing the onset and progression of lung disease in most patients with bronchiectasis.

IN A NUTSHELL

1. Bronchiectasis is a suppurative obstructive lung disorder that is characterized by thickening and dilatation of bronchial walls that leads to persistent airway inflammation and mucus retention, recurrent pulmonary infectious exacerbations and may be caused by a variety of pulmonary and systemic disorders.
2. Its pathogenesis is explained by Cole's vicious cycle model that describes how repeated infections or airways obstruction can cause continued airway inflammation and obstruction, which leads to repeated infections, that further perpetuates the inflammation.
3. Besides a detailed history and examination, high resolution chest CT scans are helpful in definitive assessment of severity and possible underlying cause of non-CF bronchiectasis.
4. Therapy with antibiotics, airway clearance techniques, mucolytics can help to prevent the progression of lung damage.
5. Outcomes for patients with non-CF bronchiectasis generally depend on the nature of the underlying disease process, the age of onset, the rapidity of progression of airway wall changes and patient's adherence to prescribed therapies.

Chapter 39.30

Lung Abscess

Kana Ram Jat, Meghna Sharma

A lung abscess is a localized central necrosis and suppuration of the lung parenchyma following microbial infection leading to formation of single or multiple cavities containing fluid and necrotic material.

EPIDEMIOLOGY

The incidence of lung abscess in children is 0.7 per 100,000 admissions per year and it is less common than adults. Advances in the field of antibiotics have drastically reduced the incidence of lung abscesses. Mortality secondary to lung abscess has also reduced and now mostly occurs in malnourished, debilitated and immunocompromised children.

CLASSIFICATION

Lung abscesses can be classified based upon the duration and etiology. *Acute lung abscess* is less than 6 weeks in duration and *chronic* is more than 6 weeks of duration. Lung abscess can also be categorized into primary and secondary. *Primary lung abscesses* are those that develop in previously healthy children, whereas *secondary lung abscesses* develop in a child with predisposing factors such as cystic fibrosis, gastroesophageal reflux, congenital thoracic malformations, airway obstruction, postoperative complications of tonsillectomy, bronchiectasis, tracheoesophageal fistula, septicemia (septic emboli), spread from extrapulmonary site (mediastinum and diaphragm), immunodeficiency or aspiration secondary to neurological illness. A primary lung abscess is almost always solitary and mostly on right side, whereas secondary abscess can be solitary or multiple and may dominate on left side. An abscess may also develop as infection or complication of pre-existing bulla or lung cyst.

ETIOLOGY

Most of the lung abscesses are polymicrobial. Anaerobic and aerobic bacteria are the main causative organisms but in rare cases, especially in immunocompromised children, parasitic and fungi have also been implicated. The aerobic bacteria causing abscess are *Staphylococcus aureus*, *Klebsiella pneumoniae*, *Pseudomonas aeruginosa*, *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Haemophilus influenzae*, *Actinomyces* and *Nocardia* species, *Mycobacterium* and gram-negative bacilli. Anaerobes are those mostly found in oral cavity like *Peptostreptococcus*, *Bacteroids*, *Fusobacterium* and microaerophilic *Streptococcus*. Nonbacterial pathogens causing lung abscess include *Paragonimus*, *Entamoeba* species and fungus like *Aspergillus*, *Cryptococcus*, *Histoplasma* and *Candida*.

PATHOGENESIS

Lung abscess begins as small areas of necrosis in a consolidation which join to form a big cavity containing necrotic debris surrounded by a thick wall of infected and inflammatory tissue. Sometimes this process may establish communication with an airway and cause partial expectoration of purulent content and a resultant air-fluid level. Lung abscess may develop in any part of the lung, but aspiration related abscess most commonly affects the dependent areas. In recumbent position right upper lobe, left

lower lobe and apical segment of both lower lobes are dependent areas. Right side is more affected than left side because of vertical bronchus. As the aspirate reaches lower airways, bacteria present in the aspirate initiate an infection which if not cleared by host defense mechanism cause pneumonitis, ultimately leading to tissue necrosis after 1 or 2 weeks. Rarely septic emboli from septic thrombophlebitis or tricuspid valve endocarditis may also lodge in the lung. Hematogenous seeding of bacteria in lung can also occur in septicemia. Histopathologically, lung abscess is a suppurative focus surrounded by fibrous tissue and mononuclear infiltration.

CLINICAL FEATURES

Clinical features are often subacute and include low grade fever, cough, sputum production, hemoptysis, anorexia, weight loss, and night sweats. Symptoms may last for few weeks before diagnosis. However, a smaller proportion of cases may present with high grade fever, respiratory distress and chest pain. Sputum may present only in big children which may or may not be foul smelling. Signs include toxic looking child, febrile, clubbing, and respiratory distress. Chest findings are decreased breath sounds, dullness on percussion, and bronchial breath sounds which can be amphoric or cavernous.

COMPLICATIONS

Acute complications are empyema formation following rupture in pleural space, pneumothorax, massive hemoptysis and respiratory failure. Other complications may include bronchopleural fistula and fibrosis of involved lung.

DIFFERENTIAL DIAGNOSIS

Lung abscess may be difficult to diagnose if associated with empyema or consolidation. Pneumatoceles, bullae or lung cyst may also lead to diagnostic confusion. An infected lung cyst may also simulate an abscess, but can usually be differentiated by thin wall of the cyst (between 1 mm and 4 mm) and no signs of inflammation. Pneumatoceles again are thin walled air-filled cyst that develops in lung parenchyma which may occur due to bacterial infection, most commonly *Staphylococcus aureus* or barotraumas. Congenital pulmonary airway malformation (CPAM), a condition caused by overgrowth of abnormal lung tissue that may form fluid filled cysts or result in the failure of the development of the tiny air sacs, may sometimes look like an abscess. Cavitary lesions can also be present in Wegener's granulomatosis, a form of vasculitis affecting small and medium vessels, but it will have other systemic manifestations also.

DIAGNOSIS

Radiology forms the mainstay of diagnosis of lung abscess. Chest X-ray characteristically shows a well circumscribed thick wall cavity with air fluid levels (**Fig. 1**). Diagnosis of lung abscess is difficult on chest X-ray if it is accompanied by empyema, consolidation or pneumatoceles. In such cases contrast-enhanced computed tomography (CECT) chest makes a definitive diagnosis and also helps differentiate between a loculated empyema, sequestration, necrotizing pneumonia, pneumatocele and congenital thoracic malformation from a lung abscess. Lung abscess looks like a radiolucent lesion with irregular and well defined thick margins that makes an acute angle with pleural chest wall (*egg on the carpet* appearance), whereas loculated empyema forms an obtuse angle with chest wall (*egg under the carpet* appearance). Pneumatoceles are characterized by localized air collection that has thin and smooth wall with or without air-fluid level. Ultrasonography

Figure 1 Lung abscess in the left lower lobe

(USG) may detect peripheral lung abscess with pleural contact or one associated with a consolidation. Detection of etiologic agent, although difficult, may be helpful to curtail empiric therapy in lung abscess. Infected hydatid cyst and tuberculosis should be ruled out in all patients.

TREATMENT

Antibiotics form the mainstay of treatment for lung abscess. Empirical antibiotic therapy is usually needed as most of the time abscess material may not be available for examination. Most useful empiric therapy for lung abscess should include drugs for both aerobics and anaerobes. The usual regimen is combination of penicillin and clindamycin. Clindamycin is preferred over metronidazole for anaerobic coverage as it has good intracellular uptake and is stable in low pH and produces excellent results. Metronidazole has failed to produce desired results despite of good anaerobic spectrum. Alternative drugs include amoxicillin with clavulanic acid, piperacillin with tazobactam, cefoxitin, or imipenem. If culture of sputum, blood or aspirated pus comes positive, then antibiotics should be modified accordingly. Parenteral antibiotic therapy should be continued for 2–3 weeks. It should be followed by oral antibiotic to complete a total duration of 6–8 weeks. Postural drainage should be done in all patients

where ever possible. In most cases, antibiotic therapy along with postural drainage is sufficient for cure of lung abscess. Patients, who are not responding to this therapy in 7–10 days, may require abscess drainage through thoracotomy, thoracoscopy or CT guided percutaneous aspiration. Lobectomy should be reserved for patients with severe abscess which fail to respond clinically and radiologically to above treatment. Massive hemoptysis, although rare in children, is another indication of surgery.

PROGNOSIS

Overall, the prognosis of primary lung abscess is good and most patients respond well to antibiotic therapy and only few patients require surgery. For secondary lung abscess, prognosis is determined by underlying predisposing condition.

IN A NUTSHELL

1. Lung abscess is less common in children as compared to adults.
2. *Staphylococcus aureus* is the main causative organism; anaerobes are also responsible in many cases.
3. Radiology is the mainstay for diagnosis of lung abscess.
4. Most of children with lung abscess require conservative treatment with antibiotics for 6–8 weeks. Penicillin plus clindamycin is the empirical therapy, to begin with.
5. Prognosis of primary lung abscess is very good, but prognosis of secondary lung abscess depends on underlying predisposing condition.

Chapter 39.31

Tracheobronchial Foreign Body Aspiration

Varinder Singh, Ankit Parakh

Tracheobronchial foreign body (TFB) aspiration is a common problem in childhood which requires quick diagnosis and management. TFB in children can present with varying manifestations ranging from acute life-threatening airway obstruction to a persistent atelectasis and localized bronchiectasis. Diagnosis and retrieval of foreign body from airways requires a bronchoscopy. Rigid bronchoscopy has been the main diagnostic and therapeutic procedure for children suspected to have a TFB, although recent literature suggests that flexible bronchoscope can be used for both purposes.

LOCATION OF FOREIGN BODY

The most common site of lodgment of TFB are the main bronchi; right main bronchus (30%) and the left main bronchus (30%), followed by the trachea (25%). Unusually TFB can be found in the bronchus intermedius, right lower lobe bronchi and left lower lobe bronchi. Since both the main bronchi are almost at the same angle at the carina in young children, TFB can lodge in either bronchi with equal rates unlike adults where the right main bronchus is shorter and straighter compared to the left. The clinical manifestation also depends on location of foreign body.

TYPES OF FOREIGN BODY

The aspirated TFB can be categorized broadly as *organic* and *inorganic*. Organic foreign bodies such as nuts and seeds are the most common type in children constituting around 80% cases. Peanut are the most common followed by gram seed, betel nut, pea nut kernel in India. Inorganic foreign bodies include plastic foreign bodies like whistles, pen cap, small parts of toys and metallic foreign body like metallic screws, nut bolts, and coins. Organic foreign bodies produce more inflammatory reaction, especially with seed, since they produce a chemical resin which can worsen the obstruction. While inert inorganic material may remain asymptomatic for long time; some sharp objects may lead to trauma to airways or various air leak syndromes.

CLINICAL SPECTRUM

Tracheobronchial foreign body aspiration is more common in younger children with almost 75% being less than 3 years of age. Young children have a higher propensity to aspirate foreign body because of oral exploration; lack of molar teeth, and poor swallowing coordination. Boys are more vulnerable and account for 65–70% of TFB aspirations. The exact reason behind male predominance is unclear. With the increasing use of head covers and scarves in the Islamic nations, aspiration of scarf pin is on the rise among young adult girls as they often hold this pin in their mouth while tying the head gear and thus risk aspiration.

The *most common symptom* is acute onset of cough, usually in the absence of any other sign of upper respiratory tract infection, and is present in more than 90% children. History of choking is a predominant feature of TFB aspiration and found in 70–80%. Presence of choking has a very high prediction for the presence of TFB, although the absence of choking does not rule out the

possibility of TFB body aspiration. Often choking accidents go unnoticed as the child may be alone or with other young children while aspirating and thus the event goes unreported. Such cases can present early if there is respiratory compromise or else present late with suppurative complications. Fever might be present in a few cases. Other important history includes acute onset respiratory distress, stridor, audible wheezing, and cyanosis. The history of change in voice should also be carefully elicited since it would indicate the presence of a laryngeal foreign body.

Clinical examination Respiratory examination would reveal stridor or a monophonic wheeze (might be unilateral in cases of a TFB in the bronchus, bilateral in cases of tracheal TFB). There would be reduced air entry on the side of the lodgment of the TFB (in cases of tracheal TFB air entry would be equal on both sides). The classical clinical triad of cough, wheezing, and decreased air entry has shown to have a low sensitivity (25–40%), but high specificity (95%) in some studies. In younger children, the aspirated TFB is often too large to enter the bronchial tree beyond carina and stays in the trachea. Such children will have no localizing feature.

Laryngeal foreign body would present with stridor with change in voice without any wheezing and reduced air entry. Tracheal foreign body can present as variable degree of respiratory distress, stridor, or acute life-threatening obstruction, but would have a monophonic wheeze and equal air entry. Foreign body in bronchial tree often presents as cough, unilateral decreased breath sounds, and wheezing. It should be remembered that TFB can be mobile and can cause variable signs with the movement of the TFB.

COMPLICATIONS

Acute complications include hypoxia and air leak syndromes (pneumothorax, hydropneumothorax, pneumomediastinum, and subcutaneous emphysema). Mortality has been well described in children with TFB aspiration. Forgotten TFB can lead to various long-term complications like recurrent unilobar pneumonia, persistent atelectasis, bronchiectasis, and bronchial stenosis.

RADIOLOGICAL DIAGNOSIS

Chest radiographs would usually be carried out in most patients with suspected TFB aspiration. Radiopaque TFB like pins, screws, etc., can easily be picked up by radiological examination but are uncommon. The most common TFB among children are not visualized directly on chest skiagrams as they are not radiopaque. However, nearly two-thirds of the cases have indirect evidence in form of overinflation of a lung or its part, or else atelectasis of a lung or its part. The indirect radiological findings of localized hyperinflation are secondary to a *ball valve phenomenon* and the atelectasis results from complete resorption of air after airway occlusion. Lung infiltrates and consolidation or air leak syndromes like pneumothorax, pneumomediastinum and subcutaneous emphysema can also be seen. Normal chest radiographs cannot exclude TFB as tracheal TFB may not produce any radiological change. Other radiographic techniques include radiographs in inspiration and expiration with the expiratory film showing air trapping, but it misses about a third or more of the cases. Fluoroscopy has also been described; would show similar findings of expiratory air trapping and reduced diaphragmatic excursion of the involved side.

There has been recent interest in multidetector computed tomography (MDCT) chest and virtual bronchoscopy for non-invasive diagnosis of TFB in children. Virtual bronchoscopy is a relatively new, noninvasive diagnostic method that gives a 3-dimensional view of the internal walls of the tracheobronchial tree through the reconstruction of axial images. The drawbacks

include radiation exposure, cost and nonavailability of the expertise. The sensitivity is not enough to recommend this at present. In the authors opinion the modality has been poorly useful and usually delays referral.

MANAGEMENT

Management of aspirated TFB depends on the location of TFB and the condition of the child. In children presenting with life-threatening TFB, basic life support (BLS) and pediatric advanced life support (PALS) guidelines should be followed. Immediate treatment of TFB by parents or caretakers may dislodge the foreign body. In infants, back slaps in a head down position with or without chest thrusts are the treatment of choice. Abdominal thrusts including the Heimlich maneuver appear more appropriate for older children.

Removal of the foreign body is the primary objective and mainstay of treatment. Rigid bronchoscopy has been the main diagnostic and therapeutic procedure for children suspected to have a TFB. Fiberoptic bronchoscopy (FOB) has been increasingly used for diagnostic purposes especially because of the high rates of negative rigid bronchoscopies. Some authors have suggested performing rigid bronchoscopies only in cases of asphyxiating TFB, radiopaque TFB and in children with clinical/radiological lateralizing signs; while in all other situations FOB is preferred. This approach will lead to best utilization of the two approaches as those with high probability of TFB undergo rigid scopy, where the extraction shall be possible at the same sitting.

Traditionally, rigid bronchoscopy under general anesthesia by the ENT surgeon is the procedure of choice for retrieving the TFB in children. Rigid bronchoscopes have the advantage of a wide working channel that permits good ventilation and control of the airway. It also acts as a conduit through which the foreign body can be removed. The availability of wide range of sizes of rigid bronchoscopes, superb optical telescopes for visualization, and the large array of ancillary instruments to retrieve TFBs has made it the favorite instrument in the management of pediatric TFB.

Pediatric flexible bronchoscope has been used, but has not gained popularity for extraction of TFB in children. Main drawbacks cited are the lack of ability to control the airway, small caliber of the suction channel and lack of ancillary instruments available to grasp the TFB. In recent years, flexible bronchoscopy has gained the popularity among respiratory endoscopist as a first choice for retrieval of foreign bodies in the children especially with availability of urological wire baskets. Flexible bronchoscopy can be performed under sedation with local anesthesia, can reach TFB lodged in distal airway and can obtain alternate diagnosis and take samples for bronchoalveolar lavage.

PREVENTION

Majority of the TFBs in children are organic food particles and lead to acute airway obstruction. Parents need to be educated regarding the factors leading to TFB aspiration in young kids like absence of moor teeth and poor swallowing coordination. There is also a need to create public awareness regarding the avoidance of nuts and various fruits with seeds in children less than 4 years. It should also be emphasized that toys should be appropriate for age and small

toy parts are a leading type of inorganic TFB. Other small objects like pen caps and so on should be kept out of reach of preschool children. Since most of the deaths secondary to TFB aspiration occur in home only, parents should be educated regarding the urgency of the condition and immediate hospitalization needs. Teaching BLS algorithms and especially Heimlich maneuver to the parents and community might reduce the chances of fatal accidents.

IN A NUTSHELL

1. Tracheal foreign body in children can present with varying manifestations ranging from acute life-threatening airway obstruction to a persistent atelectasis and localized bronchiectasis.
2. The most common site of lodgment of TFB is the main bronchi; right main bronchus; the left main bronchus, followed by the trachea.
3. The aspirated TFB can be categorized broadly as *organic* and *inorganic*.
4. The *most common symptom* is acute onset of cough, usually in the absence of any other sign of upper respiratory tract infection. A history of choking is mostly available.
5. Acute complications include hypoxia and air leak syndromes.
6. Nearly two-thirds of the cases have indirect radiological evidence in form of overinflation or atelectasis of a lung or its part. The indirect radiological findings of localized hyperinflation are secondary to a *ball valve phenomenon* and the atelectasis results from complete resorption of air after airway occlusion.
7. Diagnosis and retrieval of foreign body from airways requires a bronchoscopy. Rigid bronchoscopy has been the main diagnostic and therapeutic procedure for children suspected to have a TFB, although recent literature suggests that flexible bronchoscope can also be used for both purposes.

Chapter 39.32

Central Hypoventilation

Mahesh Babu Ramamurthy, Daniel YT Goh

Respiration is regulated to maintain oxygen, carbon dioxide, and acid-base balance within a narrow range. The homeostatic mechanism involves a myriad of complex pathways and mediators, controlled largely by the central respiratory center in the brainstem in coordination with peripheral receptors and effectors.

DEFINITION

Central alveolar ventilation is diagnosed when the PCO_2 is more than 45 mm Hg due to decreased ventilatory drive. This can be either *congenital* or *acquired* (e.g., due to drugs or central nervous system diseases like cerebrovascular accidents, trauma and neoplasms). Congenital central hypoventilation may be primary, e.g., congenital central hypoventilation syndrome (CCHS) or secondary, e.g., due to Arnold-Chiari malformation.

CLINICAL SPECTRUM

The spectrum of central hypoventilation syndromes discussed here includes: (1) CCHS, (2) Rapid onset obesity with hypothalamic dysfunction, hypoventilation, and autonomic dysregulation (ROHHAD), (3) Chiari malformation, and (4) Others: Prader-Willi Syndrome, familial dysautonomia, achondroplasia, and Leigh's disease. Central hypoventilation disorders are rare and often complex disorders that may involve alterations in mechanisms of ventilatory control and autonomic dysfunction.

CONGENITAL CENTRAL HYPOVENTILATION SYNDROME

Congenital central hypoventilation syndrome, also called Ondine curse, is a rare and severe form of central hypoventilation with autonomic nervous system dysregulation.

Etiology

A mutation in the *PHOX2B* gene (a gene that codes for a transcription factor that regulates neural crest cell migration and the development of the autonomic nervous system) is seen in more than 95% of children with CCHS. Over 90% of *PHOX2B* mutations in CCHS have an increased polyalanine repeat expansion mutation (PARM). There is a good correlation between increasing severity of disease and the number of PARMs. The remaining 10% have a nonpolyalanine repeat expansion mutation (NPARM) such as missense, nonsense, or frame shift. Certain PARMs have an autosomal dominant inheritance with incomplete penetrance. No structural central nervous system lesion is accountable for the manifestations of this syndrome have been confirmed.

Pathophysiology

The affected individuals have a lifelong impairment of arousal response to hypercarbia and hypoxemia and lack the perception of asphyxia. They lack ventilatory responsiveness to hypercarbia and hypoxia, both during wakefulness and sleep. Hypoventilation can occur both while awake and asleep in severe cases, while milder cases occur only during sleep. Gas-exchange disturbances occur predominantly during nonrapid eye movement (REM) sleep, in contrast to other sleep-related breathing disorders that are predominant in REM sleep.

Epidemiology

Congenital central hypoventilation syndrome is probably not as rare as the previous estimated prevalence of 1 case in 200,000 live births. It has been reported that nearly 1,000 children worldwide have *PHOX2B* mutation-confirmed congenital central hypoventilation syndrome.

There is no apparent racial or gender differences in occurrence. The children usually present at birth, but the diagnosis can be delayed because of variations in disease severity and a fluctuating course. Late-onset CCHS tends to present, following an infection or some other respiratory insult.

Clinical Features

The wide spectrum of clinical manifestation is related to the severity of the disorder. Infants can present with apnea at birth and many require mechanical ventilation. But some may mature and develop a pattern of breathing during wakefulness over time while apnea or central hypoventilation may persist during sleep. Symptoms of hypoventilation are more pronounced during even minor respiratory tract infections since, they do not mount respiratory responses to increased demands and they do not manifest signs like tachypnea and nasal flaring. Others may present at a later age, while some may present more subtly with right heart failure (cor pulmonale) as the first indication of CCHS. Still, others may present with unexplained apnea or an apparent life-threatening event or some may even die and be categorized as having sudden infant death syndrome (SIDS).

Associated Abnormalities

Patients may also have disorders of autonomic nervous system control, with increased frequency of cardiac arrhythmias (primarily sinus bradycardia and transient asystole), abnormalities in blood pressure, and pupil diameter control. About 15–20% of patients with CCHS also have Hirschsprung disease. Neuroblastoma may be present in about 5% of patients with CCHS. Ocular findings (abnormal pupils, abnormal irides or strabismus) can be found in up to 70% of cases.

Diagnosis and Evaluation

The diagnosis of CCHS should be kept in mind in all children presenting with hypoventilation, with no neuromuscular, cardiac or pulmonary causes. A high index of suspicion is required to make this diagnosis. A positive diagnosis of CCHS is made by:

- Careful observation of respiratory pattern and gas exchange during both wakefulness and sleep. Hypoventilation with absent or negligible ventilatory sensitivity to hypercarbia and absent or variable ventilatory sensitivity to hypoxemia is a characteristic feature.
- Testing should ideally include all aspects of routine polysomnography including electroencephalogram (EEG), respiratory effort, oronasal airflow, ECG, saturations and end-tidal CO_2 monitoring. Where polysomnography is not available, continuous 24 hour monitoring of saturations along with repeated PCO_2 measurements with an indwelling arterial line is recommended.
- Mutation analysis for *PHOX2B* mutation is required to confirm the diagnosis of CCHS.

Investigations

The following tests are useful to exclude other etiologies for hypoventilation and gas exchange abnormalities:

- Cardiac evaluation including EEG and echocardiogram.
- Pulmonary evaluation including a chest X-ray, diaphragm fluoroscopy and/or ultrasound looking at diaphragmatic paralysis or paresis.

- If there is significant hypotonia, electromyography (EMG), nerve conduction velocity (NCV) and muscle biopsy may be useful to exclude neuromuscular diseases.
- MRI of the brainstem is useful to look at brainstem lesions that can cause similar clinical picture.
- Metabolic screen including urinary amino acids and organic acids can be useful.

Management

Congenital central hypoventilation syndrome is a lifelong condition and hence, a multidisciplinary approach will provide holistic care on a long-term for these children. The main goal of treatment for CCHS is to ensure adequate gas exchange both during sleep and wakefulness. Maintaining normal gas exchange throughout 24 hours will help in reducing the risks of cor pulmonale and neurological insult from chronic hypoxia. A genotype-phenotype correlation has been shown, with increasing respiratory support required with increasing number of PRAMs. Various studies have shown that about 6–33% of children with CCHS will require ventilatory support. Since this is a life-long condition which does not improve with time, these children will require some form of assisted ventilation in the home setting in the longer term. Oxygen administration alone will improve SpO₂ levels and reduce cyanosis, but will not prevent hypercarbia and its complications. Respiratory stimulants including theophylline and dexamphetamine have not been shown to improve the ventilatory drive in this population. Ventilatory support is adjusted to maintain saturations about 95% and low normal CO₂ levels between 30 and 40 mm Hg. Very close supervision by caregivers is required 24 hours a day.

Chronic Ventilatory Support

Portable positive pressure ventilator via tracheostomy This is the most reliable and effective method, and is safe. A pressure limited ventilation is used for efficient and safe ventilation.

Bilevel positive airway pressure (BiPAP) via nasal or facemask It allows ventilation without tracheostomy, but usually limited to children above 7 years of age who require only nocturnal support.

Negative pressure ventilation It is limited by lack of portability, skin irritation and a sense of feeling chilled, hence is not preferred.

Diaphragm pacing This mode of ventilation involves electrical stimulation of the phrenic nerve that results in diaphragmatic contraction. It requires surgical implantation of bilateral phrenic nerve electrodes and a subcutaneous sensor. An external pulse generator will then dictate the respiratory rate. This makes the system very portable. Children who require 24 hour support will benefit from diaphragm pacing during the day and positive pressure ventilator at night.

Identifying and treating other associated autonomic dysfunctions including Hirschsprung disease is an integral part of management.

Long-term Prognosis

Central hypoventilation during sleep is a life-long problem. Recurrent hypoxemic episodes contribute to morbidity and complications. The main causes of death include cor pulmonale, pneumonia and aspiration. Aggressive early diagnosis and prompt institution of ventilator support improves prognosis. A disturbance of cardiac autonomic regulation in CCHS may cause sudden cardiac death and indicate the need for a cardiac pacemaker. These children will require intensive home monitoring with additional care givers and monitoring equipment. Prevention of hypoxia reduces neurological sequel and cognitive disabilities.

RAPID ONSET OBESITY WITH HYPOTHALAMIC DYSFUNCTION, HYPOVENTILATION AND AUTONOMIC DYSREGULATION (ROHHAD)

This newly defined entity is different from late onset CCHS and is negative for *PHOXB* mutations. These children typically present between the age of 1.5 and 9 years with rapid onset obesity followed by signs and symptoms of hypothalamic dysfunction including water imbalance, temperature imbalance and behavioral abnormalities. The typical presentation of hypoventilation occurs after a viral infection, with symptoms of obstructive sleep apnea and alveolar hypoventilation. Nearly half of these children will experience a cardiorespiratory arrest. Currently, ROHHAD remains a clinical diagnosis and there is no genetic testing available.

PRADER-WILLI SYNDROME

Prader-Willi syndrome (PWS) is a genetic disorder with uniparental disomy. Its features include hypotonia, developmental delay, hypogonadism, marked hyperphagia, with consequent morbid obesity and psychological problems. Temper tantrums, emotional lability, obsessive symptoms, and cognitive impairment are seen in adolescence. Daytime hypersomnolence, nocturnal sleep disturbance, obstructive sleep apnea, nocturnal hypoventilation and reduced ventilatory response to hypoxia and hypercapnia are seen in PWS.

IN A NUTSHELL

1. Central alveolar ventilation is diagnosed when the PCO₂ is more than 45 mm Hg due to decreased ventilatory drive. It can be congenital or acquired.
2. Congenital hypoventilation can be either primary (CCHS) or secondary (Chiari malformation).
3. A diagnosis of primary congenital central hypoventilation syndrome (CCHS) should be considered in all children with evidence of hypoventilation without underlying cardiopulmonary, metabolic, neuromuscular or brainstem dysfunction. These children do not manifest signs of respiratory distress such as tachypnea and nasal flaring in response to hypoxia or hypercapnia.
4. Genotype data can help in diagnosis and prognosis of children with CCHS. Genetic testing should be performed for the *PHOX2B* gene.
5. The goal of management of patients with CCHS is to provide adequate ventilation to prevent long-term morbidities such as developmental delay and pulmonary hypertension.
6. Newer modes of ventilatory support such as noninvasive ventilation and diaphragmatic pacing prevent the need for tracheostomy and therefore improve quality of life for selected children.

Chapter 40.1 Historical Aspects and Advances in Pediatric Cardiology

S Srinivasan

On behalf of millions of neonates born with simple to complex congenital heart diseases and children with acquired heart diseases but yet lucky to survive and their courageous and supportive parents, it is expected of a pediatrician to place on record in this textbook the valuable contributions in terms of commitment, compassion, concern, courage to fight against all odds, dedication, efforts, faith, foresight, innovations, sacrifice, team spirit of pioneers and trendsetters in this field which brought about revolutionary changes in diagnosis and treatment. The future will focus in gaining more understanding of genetics and molecular biology involved and in maintaining the blend of enthusiasm, scholarship, skill, coordinated team spirit and above all humanism that have always been a hallmark of the advances made over 3 centuries.

"There is nothing more difficult to take in hand, more perilous to conduct, nor uncertain in its success, than to take the lead in the introduction of a new order of things, for the innovator has for enemies all of those who have done well under the old, and lukewarm defenders in all of those who may do well under the new."

Niccoló Machiavelli (1469–1527)

THE HISTORY

The first description of a congenital heart defect was given in 1673 by Steno of Denmark which in 1888, later named by Fallot of Marseilles as tetralogy of Fallot. This paved the way for affected children who would have otherwise not lived to see another day to become fully functional adults. The remarkable advances in pediatric cardiology started after a gap of another 45 years with the publication of a painstaking and monumental work of Maude Abbott *Atlas of Congenital Cardiac Disease* in 1936. This marked

the beginning of a major era of progress in understanding the pathophysiological anatomy of diverse congenital heart defects in still births, abortion and live neonates and surviving infants beyond 1 month.

The second era of progress highlighted the need for team approach between clinicians, physiologists interested in cardio-respiratory hemodynamics and electrophysiology, radiologists and daring surgeons including those involved in animal experimental surgery and beginning of era of open cardiac surgery. This resulted in the performance of Blalock-Thomas-Taussig anastomosis to save a child with tetralogy of Fallot from John Hopkins University of Baltimore in 1944.

The third era beginning in the mid-1970s with evolving extrinsic and intrinsic cardiac repair strategies based on concurrent progress in understanding of cardiovascular anatomy, cardiac electrophysiology, echocardiographic imaging techniques and the introduction of prostaglandin therapy in maintaining the ductal patency. This era also saw the decline in the incidence of rheumatic fever and rheumatic heart diseases in children, mostly in the developed world.

The early 1990s marked the beginning of the new era of progress in cardiac development in unraveling the mysteries of genetic, molecular and teratological basis of fetal cardiac malformations and working out possible preventive strategies in the occurrence of CHDs.

The reported mortality rates following intracardiac repair of complex congenital heart defects are currently less than 4–6%. Stroke and transient and often reversible neurocognitive postperfusion *pumphead* cardiopulmonary bypass complications are seen in 2–3% of these operated children.

Table 1 summarizes the development and advances in the management of congenital heart diseases and the achievers who made it possible. In developing countries with resource constraints and where the majority of the population lives in rural areas without proper access to tertiary care centers, the availability of surgical cure has been limited. In India, there is a rapid growth discernible in the development of therapeutic and surgical facilities in big cities both in private and governmental tertiary health sectors. Increased intake of trainees both in pediatric cardiology and cardiac surgery is helping to bring out well-trained workforce to take care of these children with correctible cardiac malformations.

Chapter 40.2

Development of the Heart

S Srinivasan

The rapid embryonic growth and the consequent nutrient requirements necessitate early development of a functional heart and vascular system. The cardiovascular system in fetus becomes functional by day 21 (end of third week).

ANGIOGENESIS AND PRIMITIVE HEART TUBE

Day 18–22

Proliferation and coalescing of angioblastic endocardial cell clusters result in the formation of blood islands and capillaries in the mesoderm on either side of the neural crest of the germ disc. Blood vessels are derived from the angioblasts arising from: (1) splanchnic and chorionic mesoderm and (2) mesenchyme in the yolk sac and umbilical cord. Two pairs of blood vessel cords are thus formed by these capillaries joining together; one pair running longitudinally at the lateral embryonic edge and the other pair running medially on either side of the neural tube and joining at their cranial end. The subsequent canalization of these two cords results in two endothelial heart tubes (**Figs 1A to C**).

Pericardium

Cardiac progenitor cells after migrating to the cardiogenic area (a region anterior to the prechordal plate or head region) start proliferating from the epiblast through the lateral streak to the lateral splanchnic plate mesoderm layer; they differentiate into

cardiac myoblasts. The intraembryonic cavity over it subsequently develops into the pericardial cavity.

Myocardium and Endocardium

Simultaneously between 22 days and 28 days, a thin inner endothelial lining is formed in this fused primitive heart tube. Proliferation of splanchnic mesocardium into the pericardial celom occurs to form the primordial myocardium. A gelatinous jelly like material rich in hyaluronic acid secreted by the thick myocardium insinuates in between the endothelial tube and cardiac jelly to develop soon after into primitive atrioventricular (AV) septum and valves. The inner visceral pericardium, the epicardium, is contributed by the mesothelial cells. The heart is now suspended in the cavity by blood vessels at both ends.

Heart Tube

The lateral folding and meeting of the lateral edges of the germ disc makes the embryo to assume a tubular shape and this in turn brings the two outer tubes to come together and fuse with each other craniocaudally forming a single primitive heart tube. Though the heart starts its beats from 22nd day, the blood circulation starts only between 27 days and 29 days.

Formation of Dorsal Aortae

Blood vessels formed on either side of the midline of the embryonic plate form other clusters of proliferating and coalescing mesodermal angiogenic cells dilate as vascular sacs. These canalized sacs join to form two longitudinal dorsal aortae. Aortic arches are formed and connect these two aortae with the primitive heart tube.

Figure 2 shows main subdivisions of heart tube and their fate.

Figures 1A to C Formation of blood vessels

Figure 2 Main subdivisions of heart tube and their fate

FORMATION OF CARDIAC LOOP

23–28 Days

Atrioventricular Canal

The heart tube develops localized expansions throughout its length. Progressive elongation, alternate constrictions and dilatations of the fused primitive heart tube result in the formation of: (1) truncus arteriosus, (2) bulbus cordis, (3) primitive ventricle, (4) primitive atrium and (5) sinus venosus craniocaudally. Genetically programmed cardiac looping starts from twenty-third day and gets completed by twenty-eighth day, a major event in the development of the heart. Further elongation of the heart tube with faster growth of both bulbus and ventricle within this enclosed cavity results in bending of the cephalic portion. Initially an S-shaped tube and later a U-shaped heart tube is formed with this ventrally, caudally and rightward bending of the cephalic portion. Because of this bulboventricular loop formation, the atrium and sinus venosus tend to come dorsal to the bulbus and ventricle. The paired atrial zone seen outside the pericardial cavity develops into a common atrium and gets internalized inside the pericardial cavity. The narrowed area of the AV junction is the atrioventricular canal (AVC). Homeobox genes regulate the looping and proper organization of the heart segments.

Outflow Tracts

Bulbus cordis is relatively narrow except in its proximal third, where it becomes progressively trabeculated to form the right ventricle. The mid conus cordis gives rise to the outflow paths of both ventricles. The distal third is the truncus arteriosus which establishes continuity at its cranial end with aortic sac with its developing pair of aortic arches and pharyngeal arches—right and

left. It later gets partitioned to form the roots and proximal portions of the aorta and pulmonary artery.

Sinus Venosus

The partial fusion of the heart tubes at the caudal end occurs last and results in the proximal fused caudal sac like sinus venosus which later gets incorporated as atrium and the two distal horns, each of which receives venous return from the umbilical, vitelline and common cardinal veins.

Septum Formation

Two mesenchymal AV endocardial cushions or ridges appear one at the anterior and the other at the posterior border of AVC by the end of fourth week. Right and left AVC passage openings are formed next, with direct communication between atria and corresponding ventricles (**Figs 3A to D**). There is subsequent fusion of both anterior and posterior endocardial cushions with development of two lateral AV cushions by the end of fifth week. Direct communication is established for blood passage between AVC and primitive left and right ventricles.

Interatrial Septation (28–33 Days)

Two interatrial septae are formed one after the other during the fourth week to result in partition of the common atrium. On twenty-eighth day of intrauterine life, *septum primum*, a thin sickle or crescent-shaped endocardial fold starts growing down craniodorsally from a crest in the roof of the common atrium lateral to the sinus venosus opening. The crescent leaves a small opening below its free edge between right and left atria (ostium primum) allowing blood flow across. Two days before it fuses with the AV cushions (thirty-third day) and obliterates the *ostium*

Figures 3A to D (A) Early looping of the heart tube with formation of common AV canal; (B) Formation of dorsal and ventral endocardial cushions on walls of AVC; (C) Formation of septum by meeting and union of endocardial cushions on dorsal and ventral walls of AV canal; (D) Division of the common AV canal into right and left AV canals with beginning of development of interatrial and interventricular septa

primum, small perforations occur by apoptosis at the upper part of septum primum and they coalesce to form a second interatrial communication, the ostium secundum (**Figs 4A and B**).

A thick muscular septum, *septum secundum* arises on thirty-third day craniocaudally from the roof of the atrium to the right of the septum primum and to the left of sinus venosus valve. It stops short of fossa ovalis of the AV cushion. Thus, the interatrial septation is contributed to by both septae overlapping each other.

Formation of Interventricular Septum

Around thirtieth day (5 weeks), the *primary ventricular septum* is formed from a muscular fold which extends from the floor of the anterior wall of the ventricle in a median plane, and continues posteriorly toward the roof to meet the inferior endocardial cushion of the AVC. Dilatation of ventricles on each side results in increase in its length. With further active muscular growth this septum contributes to the muscular portion of the interventricular septum. Till the end of seventh week, there exists a free communication between the two ventricles through a crescent-shaped interventricular foramen formed between the free edge of the septum and the fused endocardial cushions.

Ventricular septation is completed with the meeting of primary muscular septum with the outflow septum and the AV endocardial cushions. The progressive growth of posterior endocardial AV cushion and right (near tricuspid opening) and left (near mitral) bulbar ridges closes the interventricular foramen by the end of 7 weeks. The membranous part of the interventricular septum is formed by the fusion of the two ridges and the endocardial cushion

outgrowth connecting both the muscular ventricular septum and the outflow aorticopulmonary septum in such a manner as to establish the normal reciprocal communications of the right ventricular outflow with the pulmonary trunk and the left ventricle with the aortic trunk (**Figs 4A and B**).

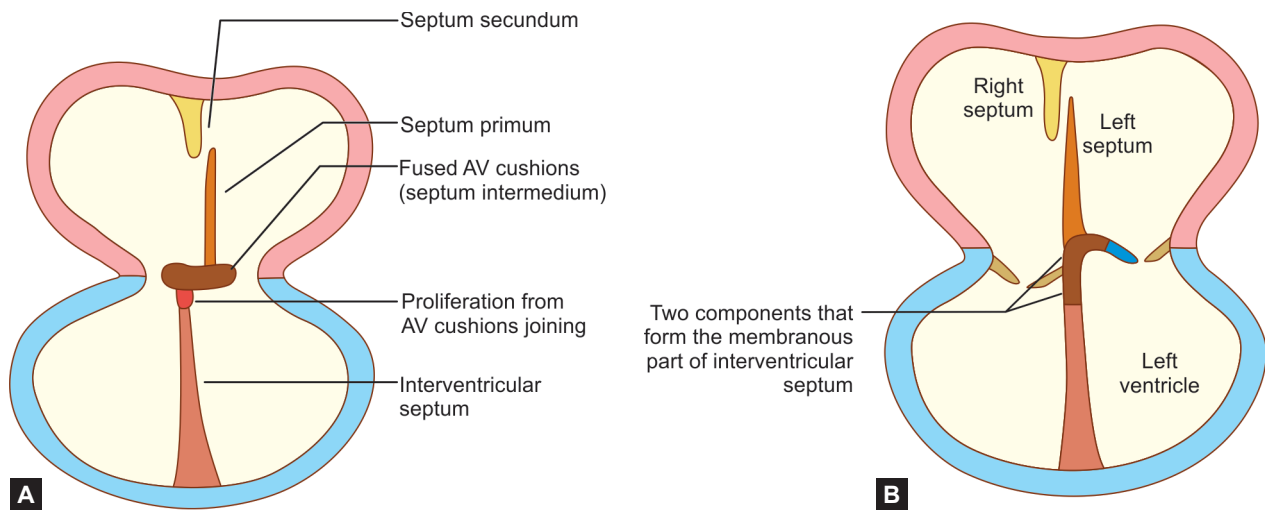

Spiral Septum Formation in the Truncus Arteriosus and Conus Cordis

From the fifth week, pairs of swellings appear on the opposite walls of the truncus, one lying superiorly on the right side and the other inferiorly on the left side. While the right superior truncal ridge grows distally and to the left, the left inferior ridge grows toward the aortic sac but to the right. The characteristics of the growth of these two truncal ridges with final fusion are so programmed so as to form a twisting of these around each other resulting in a spiral aorticopulmonary septum dividing truncus arteriosus into two main arteries: ascending aorta and main pulmonary trunk. Similarly the conal ridges grow and fuse with tissue growth from the inferior endocardial cushion closing the interventricular foramen separating the outflow areas of the ventricle (**Figs 5A to G**).

DEVELOPMENT OF MAIN ARTERIAL SYSTEM

Aortic Arch

Aortic sac contributes to the proximal aortic arch; fourth left aortic arch contributes to the main arch and the left dorsal aorta to the distal part of the aortic arch (**Figs 6 and 7**).

Figures 4A and B (A) Development of interatrial septum and interventricular septum; (B) Development of atrioventricular valves

Figures 5A to G From fifth week: (A) Ventral view of heart; (B) Transverse sections of truncus arteriosus and bulbus cordis, illustrating truncal and bulbar ridges; (C) Truncal and bulbar ridges, after removal of ventral wall of heart and truncus arteriosus; (D) Heart after partitioning of truncus arteriosus into aorta and pulmonary trunk; (E) Transverse sections through newly formed aorta and pulmonary trunk showing aorticopulmonary septum; (F) Sixth week: removal of ventral wall to show aorticopulmonary septum; (G) Spiral form of aorticopulmonary septum and aorta and pulmonary trunk twisting around each other as they leave the heart

Fate of First and Second Pairs of Aortic Arches

Major parts of both these arches disappear. A minor component of first aortic arches contributes to maxillary arteries, whereas the second aortic arches contribute to stapedial arteries.

Third Aortic Arch Arteries

Persist as common carotid artery and proximal part of internal carotid artery (both sides). It contributes to the distal part of internal carotid artery by joining with the dorsal aorta.

Fourth Aortic Arch Arteries

On the left side, it contributes to the main part of the aortic arch. On the right side, proximal part of the right subclavian artery is developed from it. The dorsal aorta connecting to the third and fourth arches disappears on both sides.

Fifth Aortic Arch Arteries

No role.

Sixth Aortic Arch Arteries

Proximal parts on both sides form the pulmonary arteries. While the distal part of the right artery disappears, the distal part of the left artery forms the ductus arteriosus connecting left pulmonary artery with arch of aorta.

DEVELOPMENT OF VEINS

Fifth Week of Embryonic Development

Three major pairs of veins are formed, e.g., (1) the vitelline veins (blood from yolk sac to the sinus venosus); (2) the umbilical veins (oxygenated blood from maternal chorionic villi to the fetus),

Figure 6 Development of great arteries and their main branches

and the cardinal veins (main venous drainage of the embryo and developing fetus); anterior and posterior cardinal veins drain the respective anterior and posterior regions.

Formation of *ductus venosus* from the left umbilical vein and the right hepatocardiac vein is mandated by the increasing placental circulation as a direct channel to bypass the hepatic sinusoidal plexus. Subsequent to birth of the child, one of the important alterations in the fetal circulation is closure of the ductus venosus to form ligamentum venosus and obliteration of the left umbilical vein to form ligamentum teres of the liver.

Superior Vena Cava

It develops mainly from the right common cardinal vein and proximal part of the right anterior cardinal vein. Inferior vena cava, azygos vein, and hemiazygos vein, are formed from right supracardinal vein, right subcardinal vein, and left supracardinal vein, respectively.

IN A NUTSHELL

1. Developmental of the heart starts from eighteenth post-connectional day.
2. Formation of heart tube is the first step.
3. Cardiac morphogenesis is almost complete by 8–10 weeks.

Chapter 40.3

The Heart and Circulation

Munesh Tomar, Savitri Shrivastava

The systemic venous return to the heart is via the superior vena cava and inferior vena cava to the right atria. In addition to both cavae, right atrium also receives blood from coronary sinus. Eustachian valve guards the opening of inferior vena cava and directs flow from inferior vena cava toward left atria. Right atrium opens into right ventricle via tricuspid valve. Tricuspid valve tensor apparatus attaches both to the ventricular septum (septophillic) and to the right ventricle free wall and is more caudally attached than the mitral valve (normal offsetting of atrioventricular valves). Right atrial appendage is broad, triangular and contains pectinate muscle in it.

Right ventricle is coarsely trabeculated, has three component: inflow, cavity and outflow tract. Right ventricle wall becomes smooth toward the outflow tract. The pulmonary valve connects right ventricle to the main pulmonary artery. Pulmonary valve is supported by the subpulmonary infundibulum, sits higher than aortic valve. Normal pulmonary valve is tricuspid and sits left and anterior to the aortic valve. Main pulmonary artery bifurcates into right and left pulmonary arteries, which connects to respective lungs. Right pulmonary artery has a straighter course, crosses posterior to ascending aorta and below the right bronchus (eparterial right bronchus) to join right lung hilum while left pulmonary artery crosses over the left bronchus (left bronchus-hyparterial) before joining left hilum. Pulmonary blood flow returns to left atrium via four pulmonary veins, two from each lung, and join posterior wall of left atrium. Left atrial appendage is crescent shaped. Left atrium is connected to left ventricle via mitral valve, which is bileaflet, does not have chordal septal attachment (septophobic). The left ventricle is smoothly trabeculated. Aortic valve is tricuspid and sits posterior and right of the pulmonary valve. Right coronary artery arises from right aortic sinus and left coronary from left aortic sinus. Both atria are separated by interatrial septum while both ventricles are separated by interventricular septum. Normal pressure range in all cardiac chambers during infancy and childhood is given in **Table 1**. **Figure 1** depicts the mature circulation.

FETAL CIRCULATION

By the end of 6 weeks of intrauterine life, the heart assumes its normal four-chambered shape. After that minor changes occur and consist mainly in the growth of the heart as a whole with increasing age of the fetus. However, significant differences exist between the fetal circulation and postnatal circulation. Fetal circulation is diagrammatically shown in **Figure 2**. Unique aspect of the fetal cardiovascular circulation is its interface with placenta.

Oxygenated blood enters the fetal circulation via placental transfer. Umbilical vein carries oxygenated blood, which enters the fetus at the umbilicus and course through to join the portal vein. The ductus venosus provides a low resistance bypass between the portal vein and the inferior vena cava so most of the umbilical venous blood shunts through the ductus venosus to the inferior vena cava. Eustachian valve directs inferior vena cava blood across the foramen ovale to the left atrium. The inferior vena caval blood comprising the streams of hepatic veins, umbilical veins, and that reaching the inferior vena cava directly from lower extremities and kidneys. Deoxygenated blood from upper extremity returns via superior vena cava to right atrium and is preferentially directed to the right ventricle. The right ventricle pumps this blood into pulmonary arteries, and across the patent ductus arteriosus into the descending aorta. Due to this streaming of blood in the fetal heart, coronary and carotid arteries get most oxygenated blood while lower body gets perfused with less oxygenated blood. Oxygen content in different cardiac chambers during fetal life is given in **Table 2**.

Figure 1 Circulation in children

Figure 2 Fetal circulation

Table 1 Pressure range in cardiac chambers in children

Chamber	Pressure (mm Hg)
Right atrium	2–6 (mean)
Right ventricle	15–25/5–8
Pulmonary artery	25/10 Mean 10–16
Left atrium	5–10 (mean)
Left ventricle	90–110/6–12
Aorta	90–110/65–75

Table 2 Distribution, oxygen saturation and partial pressures of oxygen in fetus

Site	PO ₂	Saturation
Umbilical vein	30–35	80–90
Suprahepatic inferior vena cava (umbilical vein + inferior extremity)	26–28	60–70
Superior vena cava	12–14	35–40
Right ventricle and pulmonary artery	18–20	50
Left ventricle and ascending aorta	25–28	65
Descending aorta	20–23	55

Total fetal cardiac output: 450 mL/kg/minute; Right ventricular/left ventricular output: approximately 1.3:1; Most of the available information are from fetal lamb.

During fetal life, as lungs are relatively high resistance unit, only a small amount of blood from right ventricle flows through the pulmonary arteries and veins. In postnatal life two ventricles are connected in series and therefore, the outputs of right and left ventricles are approximately identical. In the fetus very little of the right ventricular output reaches the left ventricle through the lungs, the rest goes through the ductus arteriosus into the descending aorta. The two ventricles are, therefore, acting together in parallel. The left ventricle supplying the head and upper extremities while the right ventricle supplies the trunk, viscera and the lower extremities.

CIRCULATORY ADJUSTMENTS AT BIRTH

Circulatory adjustments occur immediately following birth and continue to occur for a variable period of time following birth. This change is brought about because of a shift from placental dependence for gas exchange in the fetus to pulmonary gas exchange in the neonate.

- Loss of placental circulation with clamping of the umbilical cord, after birth, results in a sudden increase in systemic vascular resistance due to loss of the low resistance placental circulation. This tends to increase the aortic blood pressure and the left ventricular systolic pressure. The left ventricular diastolic pressure also tends to rise and increases the left atrial pressure.
- The loss of placental circulation results in a sudden reduction of flow through the ductus venosus, which closes off. The exact mechanism by which the ductus venosus closes is not known. Flow through the ductus venosus disappears by the seventh day of postnatal life.
- The loss of placental flow results in a decrease in the volume of blood returning to the right atrium. The right atrial pressure decreases. The left atrial pressure becomes higher than the right atrial pressure and the septum primum, which acts as a valve of the fossa ovalis, approximates with the septum secundum to close off the foramen ovale. Functional closure of the foramen ovale occurs very quickly. Over a period of months to years the septum primum and septum secundum become firmly adherent resulting in anatomical closure of the foramen ovale. The foramen ovale functionally closes by third month of life, though probe patent foramen ovale is found in 15–25% of children and adults.
- Sudden expansion of lungs with the first few breaths causes a fall in pulmonary vascular resistance and an increased flow into the pulmonary trunk and arteries. The pulmonary artery pressure falls due to lowering of pulmonary vascular resistance.

The pressure relations between the aorta and pulmonary trunk are reversed so that the flow through the ductus is reversed. Instead of blood flowing from the pulmonary artery to aorta, the direction of flow through the ductus is from the aorta to pulmonary trunk. During fetal life, patency of ductus arteriosus is maintained by the combined relaxant effect of low oxygen tension and endogenously produced prostaglandins. In full-term neonate, oxygen is the most important factor controlling ductus closure. When PO₂ of the blood passing through the ductus reaches about 50 mm Hg, the ductal wall constricts. This effect of oxygen may be direct or mediated by its effects on prostaglandin synthesis. The ductus of preterm baby is less responsive to oxygen. Some functional patency and flow can be demonstrated through the ductus arteriosus for a few days after birth. In full-term neonates the ductus arteriosus closes within 10–21 days. This results in the establishment of the postnatal circulation, which is in series.

APPEARANCE OF MURMUR IN NEONATES WITH HEART DEFECTS

Immediately after birth, the pulmonary pressure and resistance is equal or only slightly lower than the systemic pressure and resistance. Therefore, even if there is a communication between the two sides like atrial or ventricular septal defect or patent ductus arteriosus, there is very little flow from left to the right side. The pulmonary vascular resistance falls fairly rapidly to reach normal adult levels by 2–3 weeks in normal babies. In the presence of a ventricular septal defect or patent ductus arteriosus however, the fall in pulmonary vascular resistance and pressure is slower and reaches adult values around 6–10 weeks. Since there is very little flow across the abnormal communications like atrial or ventricular septal defect or patent ductus arteriosus, they do not manifest in the first few days of life. The ventricular septal defect or patent ductus arteriosus murmurs tend to appear by the middle or the end of the first week of life. It gradually increases in intensity as the pressure and resistance in the pulmonary circuit fall. Only by 6–10 weeks or more when the resistance may have reached its lowest value, the maximum shunt would become apparent.

In atrial septal defect, on the other hand, the right ventricular hypertrophy, present at birth, prevents a large shunt. A thick ventricle cannot expand well in diastole to accommodate a large volume of blood. The right ventricular hypertrophy takes 6 months or more to regress. Thus, the shunt of atrial septal defect takes even longer, i.e., 6 months to become apparent, before these patients are usually identified.

On the other hand, obstructive lesions like aortic stenosis or pulmonary stenosis and valvar leaks like mitral or tricuspid regurgitation would be operative from birth. Some defects as left ventricular to right atrial shunt, arteriovenous fistula are functional from birth as the flow through these defects is not dependent on the fall of pulmonary vascular resistance and these are called as *obligatory* shunts. The flows which are dependent on fall of pulmonary vascular resistance are called as *dependent* shunts. As such the murmur of obstructive lesions as well as valvar leaks would be audible immediately after birth. The clinical manifestations of atrial, ventricular or aortopulmonary communication therefore, show rapid changes in the first few weeks or months of life. Even if the evaluation of an infant at the age of 1 week has been felt to be normal, it does not rule out the presence of congenital heart disease. It is also not possible to correctly estimate the severity of the lesion in the first few weeks of life clinically.

IN A NUTSHELL

1. Fetal circulation is a circulation in parallel while neonatal/adult circulation is in series.
2. Circulatory adjustments at birth are brought about because of a shift from placental dependence for gas exchange in the fetus to pulmonary gas exchange in the neonate.
3. Changes from fetal to neonatal circulation include loss of placental circulation with clamping of the umbilical cord, increase in systemic vascular resistance, closure of ductus venosus, foramen ovale, and ductus arteriosus, fall in pulmonary vascular resistance and an increased flow into the pulmonary trunk and arteries.

Chapter 40.4

Genetic Basis of Heart Diseases

Sumaira Khalil, Seema Kapoor

Congenital and acquired heart diseases in children result in significant morbidity and mortality posing a major public health problem. Congenital heart diseases (CHDs) are one of the most common causes of birth defects in children. CHDs are defects in either the structure or function of the heart present at birth, with a worldwide prevalence of 14–15 per 1,000 livebirths. Of all the children with CHDs at birth, around 40% present with symptoms in the early/late neonatal period or within first few months after birth and get diagnosed and 33–50% need active intervention within the first year of life.

Genetic factors have been increasingly recognized to play an important causative role in CHDs. Acquired heart diseases presenting in children adolescents like rheumatic heart diseases, essential hypertension, thoracic and aortic aneurysms also have a strong genetic basis. Apart from diagnostics, therapeutic innovations like gene therapy for congestive heart failure have also been explored. Genetic insight and testing has witnessed stupendous technological sophistications and advances that make it possible to identify the genes and point mutations that are responsible for these disorders. This chapter discusses important genetic aspects of both congenital and acquired heart diseases and the developments in diagnostic and therapeutics of heart diseases in children.

EPIDEMIOLOGY

The inheritance in 80% of CHDs is multifactorial resulting from interaction of environmental factors with genetic predisposition. Chromosomal causes, Mendelian inherited disorders or nonsingle gene disorders account for about 20–30% of CHDs. This is definitely an underestimate as the studies have focused more on live born children with CHDs with abortions and stillborn being left out. These figures are however from past few decades where newer genetic diagnostic modalities had not evolved to the current sophistication like genome sequencing.

The term *polygenic* inheritance signifying the interaction of polygenic effects and environmental factors has been the usual explanation for the occurrence of CHDs. Recent studies of transmission risk of various forms of CHD do not fit this model well. The other alternative model is single gene defect modulated by random events. In order to understand the synergy between physiology and genetic-epigenetic interactions one needs to understand the development of the heart.

DEVELOPMENT OF THE HEART

In the gastrulation stage, there are two cell lineages that form the *cardiac* area. The first lineage forms the embryonic heart; the second lineage is derived from an additional *cardiac area* called the second cardiac field. *First heart field* is the crescent-shaped pool of cardiogenic progenitor cells which forms future chambers except the outflow tract. The precursor for the left ventricle is exclusively the embryonic heart whereas, the atria and right ventricle is derived from the cell of both the lineage. The efferent pathway is derived exclusively from the *second cardiac field*. The *second heart field* is the second source of myocardial cells lying medial to the cardiac crescent, and gives rise to a major portion of the heart, anteriorly to the outflow tract and right ventricle

and posteriorly to most of the atria. These findings confirm how mutations associated with CHD give rise to specific defects in heart structure by affecting specific cell lineages in the *second heart field* or in the first heart field. The dorsal neural tube gives rise to the cardiac neural crest cells (cNCC) which migrate into the caudal pharyngeal arches, pharyngeal arches 3, 4 and 6 which give rise to the future blood vessels and the outflow tract which later forms the septum. There are multiple signaling pathways that are involved in the migration of cNCC, including reciprocal signaling between cNCC and second heart field that plays an important part in the development of the outflow tract and the aortic arch system. Understandably, mutations in the genes coding for their formation or signaling would result in CHD.

GENETIC CAUSES OF CONGENITAL HEART DISEASE

With improvement in molecular genetic techniques many genes have been found to be associated with development of the heart. Mutations in a variety of single genes, gross defects in chromosomal number and subtle alterations in genomic regions are associated with a number of selected congenital heart defects and genetic syndromes. The first identified genetic causes of CHD were those with changes in chromosome number like in Trisomy 21 and Turner syndrome. Subsequently, microdeletion syndromes like 22q11.2 deletion or Williams syndrome were also recognized. With newer diagnostic tests like fluorescent in situ hybridization (FISH), multiplex-ligation dependent probe amplification and microarray technologies, larger number of deletions and duplications syndrome are being identified, e.g., 1p36 and 8p23 deletion syndromes (**Tables 1A and B**). The most common form of CHD is the ventricular septal defect which occurs in 30–40% children with CHD. The risks of recurrence in siblings and of transmission of future generations depend upon the exact mode of inheritance. Of the 5–8% of CHD which is due to chromosomal causes the recurrence risk is that of the disorder itself. In about 3% of CHD due to classical Mendelian inheritance, there is a corresponding high recurrence risk in first degree relatives. However, most CHDs have lower risks of recurrence or transmission than that predicted by Mendelian single-gene inheritance.

SPECIFIC ROLE IN DEVELOPMENT OF CONGENITAL HEART DISEASE

The concept of development of CHD arises from a defect in the genetic framework destined for the formation of heart or in the transcription factor or signaling pathway coordinating these timed events. Mutation in any of the components of the numerous regulatory genes or genes involved in the signaling pathways of cardiac morphogenetic regulatory network can cause congenital heart defects. **Table 2** depicts the genes and signal pathways regulating cardiac morphogenesis. The transcription factors are responsible for specific events in the development of the heart. T-box transcription factor gene, TBX 5 was the first single gene mutation identified giving rise to an inherited CHD, the causative gene for Holt Oram syndrome. Mutations in the NKX2-5 have been identified in families with atrial septal defect (ASD) and atrioventricular blocks, ventricular septal defect (VSD), tetralogy of Fallot and Ebstein's anomaly. The cause is haploinsufficiency (absence of one functional allele) of a developmentally important transcription factor, and this could explain the dominant pattern of disease inheritance. There have been studies showing mutations in transcription factor GATA 4 as a possible cause of inherited septation defects. Defective interaction between GATA 4 and NKX2-5 and between GATA 4 and TBX 5 might be the underlying

Table 1A Chromosomal syndromes with associated congenital heart diseases

Chromosomal syndrome	Frequency of CHD		
	All (%)	Cardiac defect	Distinctive or common features
Trisomy 13	50–80	Conotruncal CHD DORV, TOF VSD, ASD, PDA AVSD Polyvalvular dysplasia	Polydactyly Cleft lip and palate CNS anomalies (holoprosencephaly) Renal, GU anomalies Scalp cutis aplasia Microphthalmia

cause of CHD secondary to *GATA 4* mutation. Currently three interacting transcription factors are identified as regulators of heart formation, and any defective interaction between them leads to inherited CHD (**Table 3**).

GENETICS OF LATE PRESENTING CARDIOVASCULAR DISORDERS

Valvar Heart Disease

The embryological phase of cardiac development is controlled by the multiple genetic programs causing a programmed interplay

of several cell lineages and cellular process. Bicuspid aortic valve, the most common valvar malformation (1–2% of the population) is associated with later development of complications like aortic valve stenosis, regurgitation, infective endocarditis, ascending aortic aneurysm and dissection. NOTCH 2 is a transmembrane receptor functioning as a highly conserved signaling pathway in chorionic villus sampling development. Mutations in *NOTCH 1* and *GATA 5* have been implicated in aortic valvar disease.

The known association of myxomatous degeneration of mitral valve leaflets leading to regurgitation with Marfan syndrome helped in recognizing its genetic etiology—mutations in the

Table 2 Numerous genes and signal pathways regulating the cardiac morphogenesis

Genes/signal pathways	Heart development
<i>NKX2.5</i> , serum response factor (c-fos) serum response element binding transcription factor (SRF), <i>GATA 4</i> <i>TBX5</i> , <i>HAND 2</i>	Core regulatory genes of cardiogenesis and control heart looping, left-right symmetry and chamber formation
<i>FOG2</i> , vascular cell adhesion molecule 1, integrins, erythropoietin and erythropoietin receptor	Epicardial development
Notch homologue receptor (NOTCH), jagged (<i>JAG</i>), WNT, Transforming growth factor beta (<i>TGF-β</i>)2, bone morphogenetic proteins	Cardiac neural crest development in mouse
Retinoic signal acid pathway	Regulation of cardiac looping
Vascular endothelial growth factor, nuclear factor of activated T-cells, cytoplasmic, calcineurin-dependent 1; notch	Complex signal pathways implicated in formation of endocardial cushion and heart valves

Abbreviations: TGF, transforming growth factor; SRF, serum response factor.

Fibrillin 1 gene that altered the transforming growth factor (TGF)- β signaling pathway. This has also attracted pharmacogenetic modification with use of drugs like losartan.

Cardiomyopathies

Dilated cardiomyopathy (DCM) usually refers to the genetic forms of generalized cardiomegaly with heart failure—autosomal dominant in 90% and X-linked in 5–10% of cases—autosomal recessive or mitochondrial inherited forms are very rare. The genes responsible for DCM include genes encoding for sarcomere proteins such as B-myosin heavy chain, cardiac myosin binding protein C, cardiac troponin T, troponin I and myosin light chains. Two other types of cardiomyopathy, e.g., hypertrophic cardiomyopathy and arrhythmogenic right ventricular cardiomyopathy also have a strong genetic background.

Aortic Aneurysmal Disease

Both thoracic and abdominal aortic aneurysms (TAA and AAA) demonstrate a strong genetic component in their etiology. AAA demonstrate associations with variants in/nearby *SORT 1*, low density lipoprotein receptor, *DABZIP*, *LRP1*, *ELN*, *CRP*, *TGF-β* and various matrix metalloproteinase genes suggesting that aberrations of lipid metabolism and proteolytic pathway are the key contributors to the disease. Both syndromic and nonsyndromic TAA are associated with *TGF-β* pathway suggesting a strong genetic basis.

Arrhythmias

The *KCNQ1* gene on chromosome 11 in a region that contains a cluster of 6 genes that are expressed either only in the paternal or maternal allele. Mutations or imprinting of other genes is the cause of long QT syndrome.

Hypertension

Heritability estimates of blood pressure range from 30% to 60%. Monogenic hypertension/hypotension syndromes are rare. The vast majority of elevated blood pressure cases are, however, *essential hypertension* resulting from multiple genetic and

environmental factors. Large genome-wide association studies have revealed many common single nucleotide polymorphisms that associate with blood pressure. Their effects are, however, small and explain only about 2% of the variation of blood pressure even when combined. Further developments are likely to allow insight into deeper associations with factors.

Pulmonary Arterial Hypertension

Many germline gene mutations have now been described, including mutations in the gene coding bone morphogenetic protein receptor type 2 and related genes. Recent advanced gene-sequencing methods have facilitated the discovery of additional genes with mutations among those with and those without familial forms of pulmonary arterial hypertension (PAH) (*CAV1*, *KCNK3*, *EIF2AK4*). The reduced penetrance, variable expressivity, and female predominance of PAH suggest that genetic, genomic, and other factors modify disease expression.

Kawasaki Disease

Kawasaki disease (KD) is a leading cause of acquired cardiac disease of children in the developed countries. The pathogen that triggers this perplexing disease is still unknown after 40 years from the first description. Epidemiologic findings have made us believe that there are considerable genetic components in the etiology and some candidate genetic variations,

which confer susceptibility to KD or risk for coronary artery lesions have been identified. The importance of Ca^{2+} /nuclear factor of activated T-cells pathway in the pathogenesis of KD has been explored.

Rheumatic Fever

Rheumatic heart disease (RHD) is the most serious complication of heart that comprises inflammatory reactions in heart valves. Cytokines play a critical role in triggering inflammatory reactions and they activate the Janus Kinase/Signal Transducers and Activators of Transcription (JAK/STAT) signaling pathway. Polymorphisms of the STAT pathway are likely to confer susceptibility to rheumatic fever. Other susceptibility loci are being explored.

GENETIC TESTING OF HEART DISEASE

The presence of multiple extracardiac malformations, facial dysmorphism and multiple limb anomalies, development abnormalities and growth retardation acts as a marker for recognition of inherited CHDs in children at birth or later. There are several genetic tests available that can help the clinician in establishing the diagnosis. These include cytogenetic tests, FISH and DNA mutation analysis.

In all children with chromosomal abnormalities, around 30% have CHD, while less than 20% of CHD is linked to a chromosomal cause. The standard *metaphase karyotype* (450–550 bands), technique helps in identification of both number and structure. High resolution banding (550–850 bands) is more sensitive in diagnosing duplications, translocations and deletions. *FISH* has helped in the diagnosis of several syndromes like 22q11 deletion syndrome, Alagille and Williams Beuren syndrome. In individuals with major cardiac malformations and mental retardation, having a normal karyotype, *subtelomeric FISH analysis* has a very important role to play in diagnosis. Aortic arch anomalies, ASD, VSD, mitral valve insufficiency and concomitant pulmonary stenosis are the various cardiac malformations reported so far with subtelomeric rearrangements. In recent times the *microarray technique* is a method to obtain very large amounts of gene expression data with a minimum number of experiments.

DNA mutation analysis by Next Generation Sequencing (NGS) has already identified several previously inaccessible disease genes. In suspected 22q known genes like *TBX1* were used in identification. With linkage analysis, a panel of other genes were identified and put together in a chip, i.e., cardiomyopathy panel. Now, the whole human genome is mapped and is available with vast genetic information. This may help in identification of a host of genes to identify subsets of disease where pathway-specific therapies may be available in the near future.

GENE THERAPY IN HEART FAILURE

Gene therapy is aimed at correcting the key pathogenetic mechanisms in the causation of heart failure, wherein targeted drug delivery to myocardium using RNA and DNA is resorted

to as a therapeutic modality to regulate systolic and diastolic performance, reverse myocardial remodeling and restore electric stability. Though there are many inherent challenges in targeted delivery technology, gene transfer into myocardium is likely to become a clinically viable option.

EPIGENETICS

The term *epigenetic* is used to define changes in gene expression resulting from alterations in packing and/or translation of genetic material and not explained by DNA sequence changes. Epigenetic mechanisms can be acquired or inherited and constitute a means by which interactions between genes and environment occur resulting in the occurrence of the disease state. These influences lead to differential expression of similar information depending upon the environmental conditions. It is also likely to explain the influence of various factors such as smoking, drug abuse and hyperpyrexia in the development of the disease. The role of epigenetics, initiated in cancer research is now increasingly being evaluated in the understanding of development and progress of cardiovascular diseases in children and adults.

IN A NUTSHELL

1. A careful search should be made for an underlying genetic cause in CHD in children with associated dysmorphism and multiple congenital anomalies, mental retardation syndrome.
2. Sequencing technology like NGS and whole exome sequencing is likely to unravel multiple genes involved in diseases like cardiomyopathy.
3. Epigenetic and genetic influences play a major role in acquired heart disease.
4. Therapeutic gene manipulation is likely to bring about changes in decompensated stages like heart failure and may be the future for other defects.

Chapter 40.5

Systemic Disorders with Heart Disease

Anita Khalil

The involvement of the heart and/or blood vessels is known in many systemic disorders including nutritional, infective, metabolic, autoimmune, connective tissue, endocrine and neuromuscular disorders. The involvement of the cardiovascular system may become evident on careful examination and evaluation after the diagnosis of the primary systemic disease gets well-established as in muscular dystrophies or some metabolic disorders. But in a few others, the first clinical presentation of the systemic disorder itself may be an acute cardiac symptom.

NUTRITIONAL DISORDERS

Pediatricians and generalists of earlier days had experienced the dramatic response and improvement of unexplained heart failure after administration of thiamine. Similarly cardiac dysfunction and failure is not uncommon in severely anemic children and adults.

Protein Calorie Malnutrition

Earlier misconception that the heart is rarely affected in severe malnutrition has been shown to be rather ill conceived. Just as wasting of skeletal muscle is noted with inadequate intake of protein and energy, correspondingly a lesser degree of cardiac muscle involvement has also been demonstrated. As myocardial mass decreases, so does the ability to generate cardiac output. However, many of these affected individuals do not have symptoms because of the interplay of various compensatory physiologic mechanisms. Severe cardiac debility results in poor nutrition, which may produce severe myocardial atrophy, which is known as cardiac cachexia, again seen more in yester years with rheumatic mitral valvar heart disease. When such patients are being prepared for cardiac surgery, because of sudden weight loss, they are at risk of sudden death due to arrhythmias. In cardiac cachexia, there is preferential depletion of lean body mass contributing to the weight loss unlike that seen in simple starvation. Experiments on dogs suggest that protein calorie malnutrition seriously interferes with normal LV function with decreased myocardial compliance as a result of *starvation edema* and by reducing myocardial contractility.

Vitamin B₁ (Thiamine) Deficiency

Thiamine (B₁) is not synthesized in humans, and therefore its availability for necessary cellular processes hinges on its continual intake. Severe thiamine deficiency can have severe cardiac and neurologic effects; the former is reflected in a particular type of heart failure called *wet beriberi* which clearly benefits from thiamine supplementation. Clinically these babies manifest with tachycardia, tachypnea, cardiomegaly with dilatation of right heart and pulmonary hypertension.

Anemia and Renal Failure

Severe anemia is often seen to cause congestive heart failure (CHF). Presence of anemia is also associated with more severe systolic and diastolic dysfunction, a higher beta-natriuretic peptide level, increased extracellular volume, with rapid deterioration of renal function. In several controlled and uncontrolled studies, correction of anemia with subcutaneous erythropoietin (EPO) or darbepoetin in conjunction with oral and intravenous iron has been associated with improvement in clinical, cardiac and renal

status. Anemia worsens cardiac function by increasing the heart rate and stroke volume over a period of time thus stressing the heart to perform more efficiently. Reduced renal blood flow and fluid retention adds further to this stress. Longstanding anemia thus results in left ventricular hypertrophy which in turn promotes apoptosis-induced myocardial cell death. These factors operate in a vicious cycle and worsen the heart failure.

The anemia seen in one-third CHF is mainly caused by a combination of decreased renal perfusion and fluid retention. CHF-induced increased cytokine production with anemia-induced renal dysfunction leads to reduced production of EPO, resistance of bone marrow to EPO stimulation. Anemia is further aggravated by iron deficiency due to reduced intestinal absorption of iron and reduced release of iron from iron stores. Renal failure, cardiac failure and anemia therefore all interact to cause or worsen each other—the so-called cardiorenal-anemia syndrome.

INFECTIVE CONDITIONS

Congenital and neonatal viral infections usually display their clinical manifestations in highly recognizable ways. Some of these infections involve cardiovascular system and result in CHDs. Congenital rubella syndrome is associated with patent ductus arteriosus and peripheral pulmonary artery stenosis. Congenital CMV infection may result in cardiomyopathy. Influenza A viral infections may present as fulminant myocarditis resulting in cardiogenic shock and death. Antiretroviral combination therapy for HIV infection is associated with premature manifestation of coronary artery disease. In particular, protease inhibitors have been linked to metabolic changes such as insulin resistance, and abnormalities in lipid metabolism. Endothelial dysfunction is a key event in the initiation and progression of accelerated atherosclerosis which could either be caused by the infection itself or as a side effect of antiretroviral therapy. Cardiac manifestations in hypereosinophilic syndromes may range from heart failure to arterial embolism, which are caused by thickening of the endocardium leading to formation of mural left ventricular thrombus. MRI and echocardiography are able to detect fibrosis, eosinophilic infiltrate and thrombi.

CONNECTIVE TISSUE DISEASES

Marfan Syndrome

Common abnormalities include dilatation of the sinus of Valsalva, of aortic root and ascending aorta with later onset of aortic regurgitation or dissecting aneurysms. Mitral valve and left atrial endocardium often undergo fibromyxoid degeneration resulting in mitral regurgitation and mitral valve prolapse.

Systemic Autoimmune Collagen Vascular Disorders

Cardiovascular involvement may be a major manifestation in rheumatoid arthritis (RA), systemic lupus erythematosus (SLE), primary antiphospholipid syndrome (APS), and systemic sclerosis. Premature atherosclerosis has been reported in RA, SLE, APS, spondyloarthritis and other vasculitis states. Arterial stiffness, coronary arteritis, myocardial, valvar and pericardial diseases are also present in varying proportions during the natural course of these illnesses. Pericarditis is reported in 50% of cases of systemic onset juvenile idiopathic arthritis (JIA). Myocarditis occurs infrequently (1–10%) in JIA, some of which may proceed to cardiomyopathy with its attendant complications like CHF and arrhythmias. Valvar thickening leads on to mitral and occasionally aortic regurgitation. SLE may have pericarditis with pericardial effusion, myocarditis in 10–25% with resulting tachycardia, or Libman-Sacks verrucous endocarditis on mitral valve.

Neonatal Lupus Syndrome

Complete heart block is most commonly diagnosed between 18 weeks and 24 weeks of gestation. It appears that maternal anti-RO (SSA) and La (SSB) antibodies cross the placenta; the latter is a marker for risk of congenital complete heart block, and its absence implies that the child is unlikely to be affected. Mortality approaches 20% and most surviving children may develop cardiomyopathy.

ENDOCRINE DISORDERS

Hyperthyroidism

Thyroid hormones increase oxygen consumption, stimulate protein synthesis and affect carbohydrate and lipid metabolism. It also increases heart rate, cardiac contractility and cardiac output. The systolic and diastolic pressures are increased, mean pressure being unchanged. It may also increase myocardial sensitivity to catecholamines.

Juvenile hyperthyroidism may be associated with tachycardia, high volume pulses, and high systolic and diastolic pressures. The cardiac complications include arrhythmias [supraventricular tachycardia (SVT), nodal rhythm and atrial fibrillation] hypertension and heart failure. In neonates with transient hyperthyroidism, heart failure, arrhythmia (SVT) and mitral valve prolapse have been reported to occur.

Hypothyroidism

Congenital hypothyroidism (cretinism) manifests with significant bradycardia, hypotension and weak arterial pulse with nonpitting facial or peripheral edema. There is low voltage bradycardia with prolonged PR and QT intervals in the ECG and Echo studies may show cardiomegaly, pleural effusion, and asymmetric septal hypertrophy. Pericardial effusion has been reported in older children with acquired hypothyroidism.

Acromegaly

Cardiovascular manifestations include hypertension and dilated cardiomyopathy which contribute to increased mortality associated with the disease.

Pheochromocytoma

Sinus tachycardia and palpitations are the most common symptoms, but serious ventricular arrhythmias, conduction disturbances may also manifest. Reversible dilated or hypertrophic cardiomyopathy is well-established cardiac manifestation with a recent addition of Takotsubo (stress) cardiomyopathy.

Infants of Diabetic Mother

The risk of congenital heart defect is three to four times higher than that of general population, with ventricular septal defect, transposition of the great arteries, truncus arteriosus, tricuspid atresia and coarctation of aorta among the more common defects. Hypertrophic cardiomyopathy with or without obstruction is seen in 10–20% of these infants. The heart is heavier because of increased myocardial fiber size and because of hyperinsulinemia. Infants of diabetic mothers are prone to develop persistent pulmonary artery hypertension.

METABOLIC DISORDERS

Inborn Errors of Metabolism

Myocardial function is very much dependent on energy producing mechanisms like mitochondrial oxidative phosphorylation and ATP producing Krebs citric acid cycle. Hence, it is not surprising to

see either dilated or hypertrophic cardiomyopathies in many of the metabolic disorders involved in these energy producing metabolic processes.

Cardiomyopathy has been reported to be the key or the only presenting feature of fatty acid oxidation defects, e.g., deficiencies of very long chain acyl dehydrogenase, mitochondrial trifunctional protein, and carnitine palmitoyltransferase; glycogen storage disease (GSD) type II (acid alpha glucosidase deficiency) and type IX (deficiency of phosphorylase kinase b), and disorders of oxidative phosphorylation (mitochondrial myopathies). Cardiomyopathy as a secondary feature is observed in GSD types III, IV, mucopolysaccharidosis (MPS), and organic acidemias including propionic, methylmalonic, 3-methylglutaric, d-2-hydroxyglutaric and biotinidase deficiencies.

Fatty Acid Oxygen Disorders

The accumulation of intermediary metabolites of fatty acids, such as long chain acylcarnitines may be responsible for arrhythmias. Inborn errors of fatty acid oxidation should be considered in unexplained sudden death and in those with conduction defects or ventricular tachycardia.

Mucopolysaccharidoses

Excessive amounts of glycosaminoglycans accumulate in myocardium and coronary arteries. The cardiac manifestations are involvement of mitral and aortic valves in more than 50% and cardiomyopathy in 25% of MPS syndromes. Myocardial abnormalities such as septal hypertrophy, dilated cardiomyopathy and endocardial thickening are present in 25% of cases. Occasionally, systemic hypertension is also present. Coronary arterial wall thickening has also been reported in certain forms.

Homocysteinemia

Elevated plasma level of homocysteine is a strong independent risk factor for heart failure in addition to atherosclerotic disease. It causes adverse cardiovascular remodeling, characterized by interstitial and perivascular fibrosis resulting in increased myocardial thickness.

NEUROMUSCULAR DISEASES

Many familial neuromuscular and cardiovascular diseases have shared pathophysiological mechanisms caused by inherited mutations in the cardiac and skeletal muscle cell cytoskeleton, as demonstrated by advanced molecular genetic work-up. Cardiomyopathy is the most common of the cardiac involvement in neuromuscular diseases. Conduction disturbances (Emery-Dreifuss, Kearns-Sayre myotonic dystrophy) and rhythm disturbances are also life-threatening problems in these diseases.

Friedreich Ataxia

Cardiac symptoms include exertional dyspnea and chest pain appearing commonly in those with severe neurologic changes. There is ventricular hypertrophy but the endocardium and the valves are not involved. There is diffuse interstitial fibrosis and fatty degeneration of the myocardium, with compensatory hypertrophy of the remaining cells. A fair degree of atheromatous involvement is present and CHF is the terminal event in 70% of patients.

Muscular Dystrophy

Dilated cardiomyopathy is seen in both Duchenne and Becker muscular dystrophies and manifests clinically during adolescence. Exertional dyspnea and tachypnea are common symptoms and presence of CHF is an ominous terminal event.

Myotonic Dystrophy

Cardiac abnormalities are frequent with involvement of AV conduction and arrhythmias. Fatty infiltration in the myocardium and fibro fatty degeneration in the sinus node and atrioventricular conduction system may be responsible for the manifestations.

IN A NUTSHELL

1. The involvement of the cardiovascular system is known in many systemic disorders including nutritional, infective, metabolic, autoimmune, connective tissue, endocrine and neuromuscular disorders.
2. The involvement of the heart and vessels may become evident on careful examination and evaluation after the diagnosis of the primary systemic disease OR it may be the first clinical presentation of the systemic disorder.

Chapter 40.6

Cardiovascular Examination

M Zulfikar Ahamed

ARTERIAL PULSE

Arterial pulse wave is a peripheral window to look at heart and starting point for cardiovascular examination. It is related to left ventricular stroke volume, ejection velocity of blood from left ventricle (LV), and capacity and compliance of arterial system. Pulse can be central, e.g., carotid or peripheral, e.g., femoral or radial. A central pulse has an early systolic component (*percussion wave*), later peak in systole (*tidal wave*), an early diastolic component (abrupt negative wave), and a late diastolic component (dicrotic wave). Radial, femoral and other pulsations are peripheral in nature. The pulse changes its character as it becomes peripheral. It assumes greater amplitude, and greater velocity.

Carotid Pulse

It is the major central pulse and is the largest palpable proximal vessel closest to aortic valve; hence the contour resembles that of central aorta. The carotid pulse is best for evaluation of volume and character.

Radial Pulse

Traditionally, pulse rate, rhythm, volume, character and condition of vessel wall are looked for, followed by radiofemoral delay and other peripheral pulses. It is especially useful for assessing pulsus alternans and paradoxus. Pulse rate varies with age. The average pulse rate is 140/min (newborn), 120/min (infants), 100/min (children), and 80/min (adolescents). The arbitrary cut-off points for tachycardia and bradycardia are listed in **Table 1**.

Rhythm

It can be regular or irregular. Minor irregularities in relation to respiratory cycles are common in children especially when heart rate is slow: sinus arrhythmia. Abnormal irregularity in children is often due to ectopic beats, atrial fibrillation or flutter and arteriovenous (AV) blocks.

Volume

It is assessed by feeling both carotids and radials. High volume pulse is present in anemia, thyrotoxicosis, systemic hypertension, aortic regurgitation (AR), mitral regurgitation (MR), patent ductus arteriosus (PDA) and systemic AV fistula. Collapsing pulse is classically found in AR, PDA, systemic AV fistula (SAVF), truncus arteriosus, ruptured sinus of Valsalva (RSOV) and central shunt. In hyperkinetic pulse as in MR pulse pressure is normal, whereas in collapsing pulse, pulse pressure is widened. This pulse is also called Corrigan's pulse or water hammer pulse. Hypokinetic pulse is due to low cardiac output as in severe congestive heart failure (CHF), dilated cardiomyopathy (DCM), myocarditis, aortic stenosis (AS) and multiple sclerosis (MS). In AS, pulse is slow rising, has lower amplitude and the

dicrotic notch occurs later—pulsus parvus tardus. This is best appreciated in carotid artery.

Twice Beating Pulses

When two palpable pulses per cardiac cycle are felt, it is called twice beating pulse. Both pulses can be in systole (bisferiens/bifid) or one in systole and other in diastole (dicrotic). Bisferiens pulse is seen in AR, AR + AS, hypertrophic obstructive cardiomyopathy (HOCM), and occasionally in high output states. Dicrotic pulse is suggestive of impaired LV function, cardiac tamponade, or hypovolemic shock.

Pulsus Alternans

It is best appreciated in radial artery. Alternate strong and weak pulses are felt regularly. It is classically found in significantly impaired LV function and it is also detected by BP difference of more than or equal to 20 mm Hg and could be due to recruitment of more myocardial fibers after a weak contraction, or weak contraction leading to increased end systolic volumes and end diastolic volumes (EDV), and EDV operating through Frank Starling law to improve subsequent contraction.

Pulsus Paradoxus

It is defined as a marked and exaggerated fall in systolic BP (SBP) in inspiration by more than 10 mm Hg. It can be appreciated by a peripheral artery palpation also. Causes are cardiac tamponade, constrictive pericarditis ($\geq 30\%$), severe CHF (RHF), shock, asthma, and emphysema. Occasionally in the presence of tamponade, pulsus paradoxus may be absent in large atrial septal defect (ASD), in associated AR, usually acute; and in hypovolemia. Reversed pulsus paradoxus, i.e., a fall in BP in expiration can be found in HOCM.

Anisophymia

Unequal pulse between right and left radials is called anisophymia. It can occur in coarctation which is proximal to left subclavian artery, Takayasu arteritis, supraaortic AS, post-BT shunt—(classical), aortic arch syndrome, aortic dissection, and subclavian steal syndrome.

Radiofemoral Delay

Weak femorals with bounding radials are found classically in coarctation of aorta usually of thoracic descending aorta. Takayasu arteritis can cause abdominal coarctation and cause weak femorals. A difference in volume between radial and femoral may be more important than radiofemoral delay in an infant with resting heart rate of 120–140/min. In an infant it may be difficult to palpate the femoral, and dorsalis pedis examination is a useful way to exclude a significant coarctation. Coarctation with well-palpable femorals is suggestive of coexisting AR [due to bicuspid aortic valve (BAV)], coexisting PDA, or extensive collaterals to lower limb.

BLOOD PRESSURE

Blood pressure recording consists of recording SBP and diastolic BP (DBP). SBP is influenced by cardiac factors (stroke volume of LV, velocity of ejection), peripheral vascular factors (elasticity, distensibility), and volume in arteries in end diastole. DBP is influenced by peripheral vascular resistance, cardiac cycle length, and compliance of vascular tree.

Blood Pressure Recording

Blood pressure is lowest during sleep, between 2 AM and 5 AM. It has a steep rise from 6 AM to 8 AM and highest BP recordings are in the afternoon (2–4 PM). There is a difference

Table 1 Age-related cut-offs for pulse rate

Age	Tachycardia	Bradycardia
Newborn	> 150/min	< 90/min
Infant and young child	> 120/min	< 80/min
Older child	> 100/min	< 60/min

of 10–20 mm Hg in SBP between upper and lower limbs. Hill sign (difference > 20 mm Hg) is suggestive of AR. False negative Hill sign is found in AR in associated AS, or severe CHF. On standing SBP falls by less than or equal to 10 mm in adults and 5 mm in children. DBP remains the same or becomes mildly elevated on standing. Postural hypotension is defined as a fall of SBP by more than 15 mm in adult and 10 mm in children. Because LV jet preferentially is directed to innominate artery and subsequently to right subclavian artery, right upper limb BP is slightly higher than left upper limb BP. More than 10 mm Hg difference is called anisopphygmia and occurs in all conditions causing anisopphygmia. *Pulse pressure* is between 30 mm Hg and 50 mm Hg. Wide pulse pressure (> 50 mm Hg) is found in fever, anemia, thyrotoxicosis, pregnancy, SAVF, PDA, AR, Truncus and chronic coronary heart disease (CCHD) with collaterals. Narrow pulse pressure (< 30 mm Hg) can occur in CHF, AS, and dilated cardiomyopathy.

Normal Blood Pressure

Normal BP in children is less than 90th centile for age, sex and height centiles for SBP, DBP or both. Between 90th and 95th centile BP is considered *high normal* and above 95th centile BP is abnormal-hypertensive. Value above 99th centile is severe hypertension. A rule of thumb for normal BP in a child is as follows:

$$\text{SBP} : 90 + (\text{Age} \times 2) \text{ mm Hg}$$

$$\text{DBP} : 55 \pm (\text{Age} \times 2) \text{ mm Hg}$$

For SBP, boys will have BP readings 1–2 mm more than girls up to 8 years, will have same BP up to 12 years and again will have slightly higher BP (1–2 mm) up to 18 years. Boys will have DBP slightly higher: 1 mm up to 12 years compared to girls. So the difference according to sex is negligible in childhood. The cut-offs for hypertension at different ages are given in **Table 2**.

JUGULAR VENOUS PULSE

Systemic veins are a low pressure, high compliance system where pressure is between 4 cm of H₂O and 11 cm of H₂O (3–7 mm Hg). Jugular venous pressure (JVP) offers a window to right heart—both right atrium and right ventricle. Normal JVP is assessed by visualizing either external jugular vein or internal jugular vein (IJV). IJV is preferred as it has direct continuity with SVC and hence RA, it has no valves, and it is closer to RA. Right IJV is preferred as it is in direct line to SVC. Normal JVP in children is less than 3 cm from sternal angle. To assess incipient RV failure, sustained pressure is applied by palm of hand over periumbilical area or right upper abdomen for 10–20 sec when patient lies down with quiet breathing with an inclination of 45°. Elevation of JVP of more than 3 cm, or sustained elevation as long as pressure is applied, is considered abnormal. JVP is elevated in following conditions: right heart failure due to any cause; abnormal RV compliance—pulmonary hypertension

(PAH)—pulmonary stenosis (PS)—right ventricular hypertrophy (RVH), pericardial diseases, and obstruction of tricuspid valve/superior vena cava.

Occasionally severe LVH can cause bulging of IVS into RV causing a raised RV filling pressure which in turn can cause increased RA pressure leading to elevated JVP (*Bernheim effect*). Kussmaul sign refers to increase in JVP during inspiration and is suggestive of constrictive pericarditis, or severe CHF.

Abnormality of Wave

A wave is absent in atrial fibrillation. It is large in RVH due to PS-PAH, tricuspid stenosis, and RA myxoma. A giant wave is seen in AV dissociation—in complete heart block, VT (*irregular*), junctional rhythm; and SVT (*regular*). Normally *a* wave is taller than *v* wave in JVP. It can be equal in large ASD and constrictive pericarditis (with elevation of mean pressure).

PRECORDIUM

Inspection

Chest wall is examined for symmetry, precordial prominence, or deformity. Fifteen percent CHD can have associated skeletal anomalies, many of which are in the thorax. They include pectus excavatum, pectus carinatum, kyphosis, scoliosis, and Harrison's sulcus. Look for scars of previous cardiac surgeries. Following pulsations are seen: apex beat, epigastric pulsation, suprasternal, intercostals pulsations including second and third space pulsations.

Palpation

Palpable apical impulse in a normal child is produced by an anterior movement of LV during early systole. Apex beat is clinically the lowermost and outermost definite cardiac impulse felt over precordium and generally reflects LV activity. Normal apex beat is located in fourth left intercostal space (ICS) in midclavicular line—up to 2 years, and in fifth left ICS in 1 cm medial to midclavicular line—beyond 4 years. It is a gentle nonsustained tap, occupies only one intercostal space with a diameter of less than 2.5 cm, and lasts for less than half of systole.

Displaced apex beat indicates cardiomegaly, usually of LV type. Lateral displacement can also occur in scoliosis, straight back syndrome or any intrathoracic pathology like pleural effusion, pneumothorax, congenital lobar emphysema, without true cardiomegaly. In a *hyperkinetic* apex beat, the impulse is forcible and usually lifts examiner's finger tips above the plane of ribs. The duration remains the same: less than 50% systole. This is seen in LV volume overloading conditions [PDA, ventricular septal defect (VSD), SAVF, MR, AR, anemia, thyrotoxicosis and beriberi]. *Heaving* (sustained) apical impulse lifts the fingers markedly and duration of outward impulse is more than 50% systole—it is sustained. The duration of sustained apical impulse is a function of LV ejection time. It is due to pressure overload (AS, CoA, hypertension) but can also occur in other situations (MR, AR, DCM). *Tapping apex* is somewhat similar to normal apical impulse but is more pronounced. It is felt in MS and ASD. Third heart sound (S₃) can be palpated in severe MR and DCM. Palpable S₄ is found in AS, acute MR, hypertrophic cardiomyopathy (HCM), and long-standing hypertension.

Right ventricular activity can be assessed by presence of parasternal heave and epigastric impulse. Parasternal heave or lift can be graded empirically based on amplitude of the lift. The lift can be sustained as in PS or PAH or less well-sustained as in ASD, PR. Left parasternal lift or heave can also be due to severe MR when the systolic rise in LA causes an expansile impulse which can be transmitted to anterior chest wall. It is more diffuse and late systolic in timing.

Table 2 Definite hypertension cut-offs

Age (Years)	Boys		Girls	
	SBP	DBP	SBP	DBP
1–3	> 110	> 55	≥ 107	> 65
4–6	> 115	> 75	> 112	> 75
7–9	> 115	> 80	> 115	≥ 80
10–12	> 125	> 80	< 125	≥ 80
12–15	> 130	> 85	> 130	≥ 80

Abbreviations: SBP, systolic blood pressure; DBP, diastolic blood pressure.

Precordial pulsations can be palpated in suprasternal notch (AS, AR, CoA, aortic aneurysm), in second left space (PAH due to any cause), third left space (Ebstein, EMF), and intercostal spaces (hyperkinetic cardiac states). Thrill can be palpated at the apex; left or right sternal border, suprasternal notch, carotids, or in infraclavicular area.

Percussion

It is not very useful in children and may be difficult to perform in infants. Traditionally both right heart border and left heart border are percussed out and occasionally second left space. Right heart border is displaced in conditions of significant RA enlargement, and pericardial effusion. Left heart border is displaced in cardiomegaly, and pericardial effusion.

HEART SOUNDS

First Heart Sound (S_1)

It is a medium high-pitched sound which phonocardiographically has two components. The second component corresponds to mitral valve closure (M_1) and third component to tricuspid valve closure (T_1). Clinically M_1 and T_1 make up S_1 . Normally M_1 is the dominant component and S_1 is best appreciated at apex (mitral area). M_1 - T_1 distance is less than 20 ms and human ear cannot separate them out and hence S_1 is heard normally as a single sound. S_1 is maximally heard at apex and S_2 at pulmonary area. If S_1 heard at apex is louder or equal to intensity of S_2 at PA, it is loud. It is often subjective in evaluation.

Soft S_1 is found in prolonged PR interval, bradycardia (occasionally), chronic AR, chronic MR, acute AR, flail mitral valve, DCM, viral myocarditis, rheumatic carditis, proximal left bundle branch block (LBBB), extracardiac-obesity, emphysema, pericardial effusion and calcific MS. *Loud S_1* is found in MS, TS, LA myxoma, mitral valve prolapse (MVP), tachycardia, short PR interval [Wolff-Parkinson-White syndrome (WPW)] and ASD. *Split S_1* is classically found in Ebstein anomaly, large ASD (occasionally), and right bundle branch block (RBBB). *Reversed split S_1* (T_1 M_1) is quite rare, found in LA myxoma.

Second Heart Sound (S_2)

It has two components: aortic (A_2) and pulmonic (P_2). Normally S_2 is best heard at left upper sternal border, is split in inspiration, and single in expiration. P_2 is softer than A_2 and P_2 is not heard at apex. In inspiration A_2 - P_2 distance is more than 20–30 ms and is appreciated as two components while in expiration the A_2 - P_2 distance is less than 20 ms and is appreciated as a single sound. S_2 is a high pitched sound, best appreciated by diaphragm. The physiological inspiratory widening of S_2 split is due to increased pulmonary artery hang out interval, increased RV ejection time, and decreased Q-A2, i.e., early A2.

Loud S_2 A_2 is loud in systemic hypertension, aortic root dilatation, L-transposition of the great arteries (TGA) (anteriorly placed aorta) and TOF (sometimes). Loud P_2 is present in PAH and ASD without PAH.

Soft S_2 A_2 is soft in severe valvar/supravalvar AS, calcific aortic valve, and AR. P_2 is soft in PS, TOF, and TGA. Wide split S_2 (A_2 - P_2 > 60s in expiration) can be due to early A_2 in VSD, MR and late P_2 in PAH, PS, pulmonary embolism, RBBB, LV ectopic and LV paced beat. Wide-split can also occur due to increased hangout interval in ASD, Ebstein, total anomalous pulmonary venous return (TAPVC) and PS.

Wide and fixed split is characteristic of ASD and severe RV failure. *Reversed split* (P_2 - A_2): *Delayed A_2* -proximal LBBB, right ventricle (RV) pacing, RV ectopic, AS, hypertension, and coronary

artery disease (CAD). Reverse split is also seen in PDA and poststenotic dilatation of AS, due to decreased impedance in aorta. Early P_2 is a feature of right-sided WPW.

Single S_2 can be because of No A_2 (hypoplastic left heart syndrome, aortic atresia), No P_2 (pulmonary atresia, truncus arteriosus, absent pulmonary valve), P_2 masked/very soft—(TOF, TGA, severe PS), or A_2 - P_2 occur together (severe PAH, Eisenmenger VSD, primary PAH).

Third Heart Sound (S_3)

It is a low pitched sound occurring during the rapid filling phase of diastole. The A_2 - S_3 interval is between 120 ms and 200 ms and hence it is not a very early diastolic sound. It is normally heard in infancy, childhood and adolescence and is abnormal beyond 40 years. It is also called a filling sound, ventricular diastolic gallop or protodiastolic gallop.

Pathological S_3 is found in all causes of LV dysfunction, large left to right shunts: VSD, PDA, atrioventricular septal defect, chronic AR, MR, restrictive cardiomyopathy, DCM, myocarditis, rheumatic carditis, constrictive pericarditis (*pericardial knock*), PAH, systemic hypertension, anemia, thyrotoxicosis, and systemic AV fistula.

Pericardial knock is an early, loud, higher pitched S_3 in constrictive pericarditis. A_2 -PK distance is usually 80–110 ms. It has a clicking quality and is due to marked elevation of filling pressures associated with increased velocity of rapid filling phase.

Fourth Heart Sound (S_4)

It is a low frequency sound. It is also called atrial sound, atrial gallop and presystolic gallop. However, it is ventricular in origin. It precedes S_1 . In children S_4 is abnormal. It is absent in AF. It can be left-sided: increases on expiration, right sided: increases on inspiration. Causes in childhood are: HCM, aortic stenosis, anomalous left coronary artery from the pulmonary artery (ALCAPA) with CAD, acute AR, DCM, acute MR, AV block, and systemic hypertension. S_4 is usually looked for in left lateral position with the bell and is sometimes palpable. RV S_4 is found in severe PAH.

Clicks

Clicks are sharper, higher pitched sounds heard in systole. Clicks can be ejection clicks or nonejection clicks. Ejection clicks originate from either, semilunar valves aorta, or pulmonary artery. Causes are aortic valve stenosis (BAV), pulmonary valve stenosis; systemic hypertension, aortic dilatation, AR, aortic aneurysm, TOF (due to aortic dilatation), PAH and idiopathic dilatation of pulmonary artery.

Valvar ejection clicks are due to sudden doming and snapping of semilunar valve during ejection and nonvalvar clicks are due to tensing of dilated great vessels.

Aortic valve ejection click due to BAV or AS at valvar level. It indicates valvar nature of AS and mobility of valve. Click is constant in expiration and inspiration, i.e., constant ejection click. It is heard in AS, BAV and truncus.

Pulmonary valve ejection click is phasic in nature, i.e., increases on expiration and decreases in intensity in inspiration in contradistinction to the general rule that all right-sided cardiac auscultatory events increase in inspiration. S_1 -EC distance progressively decreases as PS progresses. Ejection click can occur both in PS and PAH. In PS, as it becomes severe, EC occurs earlier, as PAH progresses EC occurs later. In PS click is phasic, while in PAH it is usually constant. **Table 3** summarizes differences between aortic and pulmonic click.

Table 3 Aortic versus pulmonary click

	<i>Aortic click</i>	<i>Pulmonic click</i>
Maximum at	Aortic area, apex	Pulmonary area
Conduction	Carotids, widely	Localized
Relation to respiration	Constant	Phasic
Additional features	Low volume pulse	Normal volume pulse
	Left ventricular apex	Left parasternal heave
	Thrill at aortic area	'a' wave in JVP
	Paradoxical split	Thrill at pulmonary area
		S ₂ loud with wide split

Nonejection click is a high pitched sound which could be slightly lower pitched than ejection click. It is classically found in MVP and tricuspid valve prolapse. It is usually midsystolic in timing and can be late systolic in timing also. Mid-systolic nonejection sounds (clicks) also can be found rarely in LA myxoma, adhesive pericarditis, and left pneumothorax.

OPENING SNAP

It is pathognomonic of atrioventricular valve obstruction, classically MS. It is a crisp, high pitched sound heard at apex, and best appreciated between apex and left LL sternal border. It may be widely conducted if severe MS is present. It represents mobility of the valve and is due to sudden arrest of doming mitral valve. A₂-OS interval is 40–160 ms, and it is the earliest diastolic sound. As MS becomes severe A₂-OS interval shortens. It also occurs in TS and atrial myxoma. Functional snap in diastole can be heard in large ASD, VSD, thyrotoxicosis, tricuspid atresia with large ASD, severe MR, TR, HOCM, and MVP.

Prosthetic Valve Sounds

Usually from mechanical valves can occur in children who have undergone mitral or aortic valve replacement. Sounds can be opening and closing and is more prominent with ball and cage valves than disc valves. Sharpness of the valve clicks indicates the health of the valves. Bioprosthetic valves do not have an early systolic sound.

Pacemaker Sound

Children with permanent pacemaker implant have a pacemaker sound which is extracardiac in origin due to stimulation of intercostal muscles and is high pitched.

Pericardial Rub

Is a high pitched, leathery, scratchy murmur best heard over left lower sternal border. It has three components: presystolic, systolic, and late diastolic. Usually rub is constituted by presystolic and systolic elements causing a to and fro nature of the rub. Rub need not disappear with pericardial fluid collection.

HEART MURMURS

Murmur is the most frequent reason for referral for a child or infant with suspected heart disease: whether congenital or acquired. Yet many CHD—both benign and malignant—can present with hardly any murmur. In some CHD, a cardiac murmur is either not essential or useful for the diagnosis, example being ASD and

coarctation of aorta. But a murmur still continues to be a major marker for heart disease and also has significant localizing value—in localizing the clinical diagnosis. In infants with cardiac murmur, one-fourth presented before 2 weeks and one-third presented only after 3 months. Detection of a heart murmur should prompt one to initiate a complete evaluation of an infant or child. Murmurs can be systolic (between S₁ and S₂), diastolic (between S₂ and S₁), or continuous. They can be further classified as organic (**Box 1**) or innocent.

BOX 1 Murmur likely organic when:

- There is a diastolic murmur
- There is a continuous murmur
- Murmur is of Gr 3/6 or more
- Murmur is either pansystolic or early systolic
- When S₂ is abnormal
- When associated CVS findings are present.

Systolic Murmurs

Early Systolic Murmur

It starts with S₁ (S₁ coincident) and extends variably into systole and stops short of S₂. It is usually decrescendo. Causes are acute MR, TR with a normal right ventricular systolic pressure, very small, restrictive VSD, and very large, unrestrictive VSD with significant PAH.

Mid Systolic Murmur

The murmur starts a little after S₁, and usually ends before S₂. Majority of such mid systolic murmurs are ejection systolic murmurs, i.e., it is due to phasic flow through LV and RV outflow tract. Causes include AS, PS, PAH, ASD, aortic root dilation and Still's murmur.

Late Systolic Murmur

The murmur begins well after S₁, begins in mid or late systole and travels variably into systole. It is classically found in MVP and also found in TVP and has no ejection quality.

Pansystolic Murmur (Holosystolic)

It begins with S₁ (S₁ coincident) and occupies all of the systole up to S₂ (or S₂ on its side of origin) and is constant in shape and amplitude usually. Examples include VSD, aortopulmonary window, PDA in infancy, MR and TR.

Diastolic Murmurs

Early Diastolic Murmur

It is S₂ coincident murmur. It begins with S₂, is decrescendo in nature and travels variably into diastole. Examples are AR and PR.

Mid Diastolic Murmurs

It starts in mid-diastole and occupies variable phase of diastole. They are usually low pitched murmurs. It occurs in MS, TS, LA myxoma, MR, TR, VSD, PDA, ASD (flow related), and AR (Austin Flint murmur).

Late Diastolic Murmur

It is also called presystolic murmur which ends with S₁. It commonly occurs in sinus rhythm only in stenosis of mitral or tricuspid valves.

Continuous Murmur

Continuous murmur begins in systole, continues without interruption into diastole—into all or part of diastole. It usually peaks around S_2 . Continuous murmurs are generally generated when blood flows from one (high pressure) vascular bed to another (low pressure) vascular bed without interruption (**Tables 4 and 5**). It is to be differentiated from to and fro murmur which is interrupted at some point of time (**Box 2**).

Conduction of the murmur can be often useful in diagnosis. Murmurs of MR conducts to axilla, back and occasionally to base; PS conducts along supraclavicular area to acromion, base of neck; AS conducts to carotids, and VSD conducts along sternal border, widely heard in infants.

All heart lesions may not be associated with a murmur. There are several heart defects where the murmur is either absent or insignificant (**Table 6**).

BOX 2 To and fro murmurs

- Ventricular septal defect with aortic regurgitation
- Absent pulmonary valve syndrome
- Aortic stenosis with aortic regurgitation
- Pulmonary stenosis with pulmonic regurgitation.

Table 4 Continuous murmurs

Innocent murmur	Organic murmur	
	Acyanotic conditions	Cyanotic conditions
1. Venous hum	1. PDA	1. Pulmonary AV fistula
2. Mammary	2. RSOV	2. PDA in CCHD
Soufflé	3. AP window (in 10%)	3. Aortopulmonary collaterals
	4. Coronary AV fistula	4. Truncus arteriosus
	5. Systemic AV fistula	5. Unobstructed supracardiac TAPVC
	6. ALCAPA	6. BT shunt in CCHD
	7. Aorticoatrial fistula/tunnel	7. ASD with mitral atresia
	8. Lutembacher with small ASD	
	9. Coarctation of aorta	
	10. PA branch stenosis	

Abbreviations: PA, pulmonary artery; TAPVC, total anomalous pulmonary venous connection; BT, Blalock-Taussig; CCHD, cyanotic congenital heart disease; PDA, patent ductus arteriosus; RSOV, ruptured sinus of Valsalva; AP, aortopulmonary; AV, arteriovenous; ALCAPA, anomalous origin of left coronary artery from pulmonary artery; ASD, atrial septal defect.

Table 5 Variation in murmur intensity with maneuvers and drug (Hemodynamic auscultation)

Increases in expiration	Left ventricular heart sounds LVS_3 , LVS_4 Murmurs of MR, MS, AS, AR
Increases in inspiration	Right ventricular heart sounds LVS_3 , LVS_4 Murmurs of TR, TS, PS, PR
<i>Variation of auscultatory heart sounds and murmur with postural changes</i>	
Increases on standing	HCM, MVP
Decreases on standing	AS, PS, innocent
<i>Variation with squatting</i>	
Increases	AR, MR, AS, PS, TR
Decreases	MVP, HCM
<i>Variation with handgrip</i>	
Increases	MR, AR, VSD, MS
Decreases	MVP, HCM
<i>Variation with Valsalva strain</i>	
Increases	HCM, MVP
Decreases	AS, PS
<i>Variation in systolic murmur with amyl nitrite inhalation</i>	
Increases	ASD, HCM, AS, TR, PS
Decreases	MR, AR, VSD, PDA, TOF
<i>Variation in diastolic murmur with amyl nitrite inhalation</i>	
Increases	MS, PR (Nonhypertensive)
Decreases	AR, AFM, PR (PAH)

Abbreviations: LVS, left ventricular systolic; MR, mitral regurgitation; MS, mitral stenosis; AR, aortic regurgitation; AFM, Austin Flint murmur; RAH, right atrial hypertrophy; ASD, atrial septal defect; HCM, hypertrophic cardiomyopathy; MVP, mitral valve prolapse; TR, tricuspid regurgitation; TS, tricuspid stenosis; AS, aortic stenosis; PS, pulmonary stenosis; PAH, pulmonary hypertension.

Table 6 Heart defects with absent/insignificant murmur

<i>Infancy</i>	d-TGA, severe TOF, PA with VSD, pulmonary atresia with intact IVS, obstructed TAPVC, severe CoA, aortic atresia, myocarditis, dilated cardiomyopathy, EFE, Pompe disease, ALCAPA, HCM, Ebstein's anomaly
<i>Childhood</i>	Dilated cardiomyopathy, viral myocarditis, coarctation of aorta, severe TOF with high PCV, pulmonary AV fistula, hypertensive heart disease, pericardial effusion, constrictive pericarditis
PA with VSD: pulmonary atresia with VSD	

Abbreviations: EFE, endocardial fibroelastosis; HCM, hypertrophic cardiomyopathy; TOF, tetralogy of Fallot; PA, pulmonary atresia; VSD, ventricular septal defect; IVS, interventricular septum; TAPVC, total anomalous pulmonary venous return; ALCAPA, anomalous origin of left coronary artery from pulmonary artery.

Chapter 40.7

Electrocardiogram

BRJ Kannan

Electrocardiogram (ECG) is a simple and useful tool in the diagnosis and management of heart diseases in children. It also gives important clues regarding presence of dyselectrolytemia. Its most important role is in detection and management of arrhythmias. With its inherent limitations in the diagnosis of structural heart disease, it provides information regarding the pressure and volume overload changes in cardiac chambers, supplementing the clinical and chest X-ray findings.

BASICS OF RECORDING AND INTERPRETATION

While recording ECG in a small child, limb lead electrodes should be placed more proximally to reduce motion artifacts. The usual 12 lead ECG is not enough; additional V3R or V4R leads have to be recorded in children with suspected congenital heart disease. Standard gain (10 mm/mV) is used. If the QRS voltages are very large, then the gain might be halved.

The ECG is recorded at a paper speed of 25 mm per second. The time or duration of a wave is measured in milliseconds or seconds. Each small square represents 40 ms (0.04 seconds). The voltage is measured in small squares or millivolts (mV). Each small square represents 0.1 mV. Intervals should be hand measured, as the computerized systems are often inaccurate, especially in the neonates.

Intervals in children increase with increasing age, reaching the adult normal values by 7–8 years of age. The PR interval is measured from the onset of the P wave to the onset of Q wave or R wave (if no Q wave is present). It is often best measured in lead II. The duration of QRS complex is measured in the lead with an initial Q wave. The QT interval is often best measured in leads II, V5 and V6 and the longest value should be used. Corrected QT (QTc) is calculated using Bazett's formula.

$$\text{Corrected QT} = \text{QT interval} / \sqrt{\text{RR}}$$

Heart Rate Calculation

$$\text{Heart rate} = \frac{1,500}{\text{Number of small squares in a RR interval}}$$

For example, if there are 15 small squares between two consecutive R's, then the heart rate is 100/min (1500/15).

Axis Detection

Select leads aVF and I. Determine if the net QRS voltage is positive or negative in these leads. For example, if the R wave height is 10 mm (above the isoelectric line), and S wave height is 3 mm (below the isoelectric line), then the net QRS voltage is positive (+7). If the R wave is short and S wave is longer, the net QRS voltage would be negative (Fig. 1). The QRS axis can be located using the rules given in Box 1.

At birth, right axis deviation of mean QRS vector is the rule. The axis becomes normal by 1 year of age. Hence, normal or leftward QRS axis is abnormal in the neonatal period and early infancy. Common conditions with leftward axis of QRS vector are *tricuspid atresia* and *AV septal defects*. QRS axis can be normal or

Figure 1 Narrow QRS tachycardia. There is a P before each QRS and this could be wrongly labeled as sinus tachycardia. The Ps are inverted in the inferior leads suggesting that it is nonsinus rhythm. This long RP tachycardia is called permanent junctional reciprocating tachycardia

BOX 1 Detecting the axis

Lead I	Lead aVF	Interpretation	Comment
Positive	Positive	Normal axis	Abnormal in neonates and early infancy
Negative	Positive	Right axis deviation	Normal in neonates and in early infancy
Positive	Negative	Left axis deviation	Abnormal at any age
Negative	Negative	North-west axis	Abnormal at any age

leftward even at birth in very premature babies (< 28 weeks) as RV dominance is not a feature at this age.

NORMAL VARIATIONS AND RELATED ABNORMALITIES

Many tables of ECG standards for various measurements are available. However, the practical utility of these tables is limited. The salient age-related changes that one needs to know are as follows:

- Normal HR in the neonates varies between 120/min and 230/min; it increases further by first or second month of life and gradually decreases over the next 6 months. Resting heart rate is about 120 beats/min at 1 year, 100 beats/min at 5 years and reaches adult values by 15 years.
- Appearance of secondary *r* waves (*r'* or *R'*) in right chest leads is normal in neonates.
- Dominant R in right precordial leads can persist up to 6 months to 8 years; in the majority, the R/S ratio in lead V1 becomes less than 1 by 4 years.
- Q waves are normally seen in leads II, III, aVF, V5 and V6.
 - If Q waves are seen in other leads, it is abnormal.
 - Presence of Q wave in inferior leads (II, III and aVF) is due

to clockwise loop of initial QRS vector. This finding is seen in majority of congenital heart diseases also.

- When Q waves are absent in inferior leads but are seen in leads I and aVL, it is due to counterclockwise loop of the initial QRS vector. This is a feature of tricuspid atresia, atrioventricular (AV) canal defects and inlet ventricular septal defect (VSD).
- Deep Q waves in lateral leads might point toward underlying anomalous origin of left coronary artery from pulmonary artery.
- QT interval is highly variable in the first 3 days of life. If the corrected QT is more than 0.44 seconds (440 ms), it is abnormal.
 - Prolonged QT interval: Common causes: Hypokalemia, hypocalcemia, hypothermia, and cerebral injury.
 - Drug-induced QT prolongation has to be ruled out (e.g., macrolide antibiotics, trimethoprim, cisapride, etc.).
 - Consider congenital long QT syndromes, if clinically relevant and other known causes are ruled out (European Society of Cardiology).
- T wave in lead V1 can be upright at birth and it inverts by 7 days and typically remains inverted until 7 years of age. Upright T waves in right precordial leads (V1-V3) between ages 7 days and 7 years usually indicate right ventricular hypertrophy even if the voltage criterion is not fulfilled.
- Atrial and ventricular extra systoles are common and are typically abolished with exercise. Also, sinus arrhythmia is very common and there could be irregularly irregular rhythm (**Fig. 2**). The heart rate slows in expiration and speeds up in inspiration. Some children would present with significant sinus bradycardia. Both these conditions are due to excessive vagal tone. Exercise consistently increases the heart rate and the rhythm becomes regular in these children.
- Sinus pauses as long as 800–1,000 ms can be seen especially during feeding, sleep, defecation or other times of increased vagal tone. At times, periods of junctional rhythm, i.e., narrow QRS complexes without preceding P waves may also be seen.

Figure 2 There is significant irregularity of the rhythm. However, all QRS complexes are preceded by P waves with constant PR interval. This is due to sinus arrhythmia. Note the ST-segment elevation with concavity facing upward due to early repolarization. Both the findings are normal in children

- **Wandering pacemaker:** Change in P wave axis and morphology in different beats due to the shift of pacemaker from the sinus node to other sites. It is a nonpathological finding.
- **Early repolarization:** Some children especially in the adolescent age group would show ST segment elevation of 1–4 mm with the concavity facing upward (**Fig. 2**). They can also have terminal T wave inversion.

P Wave

P wave amplitude varies very little with age. Unlike QRS axis, P wave axis is normal (positive in both lead I and aVF) from birth due to sinus nodal origin of the atrial impulse. If the P axis is different, it indicates ectopic atrial rhythm, i.e., the atrial impulse arises from some other site. Low atrial origin of the rhythm is common in congenital heart disease where the P waves are typically negative in inferior leads (II, III and aVF). In children with situs inversus, right axis deviation of the P wave is seen (**Fig. 3**).

Right Atrial Enlargement

P wave amplitude is increased to more than 0.25 mV (2.5 mm) with a relatively normal P wave duration (*tall and peaked P waves*). The changes are best visualized in lead II. Tricuspid atresia, pulmonary atresia with intact ventricular septum and severe pulmonary stenosis are commonly associated with right atrial enlargement.

Left Atrial Enlargement

The changes are best visualized in lead V1 where the terminal negative deflection is increased (> 0.1 mV) and prolonged (> 40 ms). Prolonged P wave duration with increased notching can be seen in lead II due to left atrial enlargement but it is less specific. Mitral atresia and post-tricuspid shunts [VSD, patent ductus arteriosus (PDA), aortopulmonary window] show left atrial enlargement.

PR Segment

PR segment reflects the time taken by the depolarization impulse to travel across the atrium and the AV node. AV block results in prolongation of the PR interval.

First degree block Prolonged AV interval.

Second degree block, Mobitz Type I (Wenckebach type) With each successive beat, the PR interval lengthens resulting in a dropped QRS. This could be a normal finding and does not usually indicate an adverse prognosis.

Second degree block, Mobitz Type II The PR interval is normal or mildly prolonged but it is constant in successive beats. There is sudden, intermittent loss of conduction resulting in dropped QRS. This is always pathological, carries high-risk to progress to complete AV block.

Third degree AV block This is also called as complete heart block (CHB) where no atrial impulse is conducted to the ventricles. Atrial rate would be higher than the ventricular rate with complete AV dissociation (**Fig. 4**). If the escape rhythm originates near the His bundle, the resulting QRS would be narrow. If the escape focus is lower down, the resultant QRS complex would be broad. Congenital CHB is often not associated with any underlying congenital heart disease. About 2–5% of mothers with autoimmune antibodies have children with CHB and this condition carries a high mortality risk especially in the first 3 months. CHB can be also seen in children with congenitally corrected transposition of great arteries and AV canal defects. Acquired CHB can be seen in myocarditis, digitoxicity, following cardiac surgery and rarely, after interventional procedures such as catheter closure of the membranous VSD.

Causes of Short PR Interval

Common causes are Wolff-Parkinson-White syndrome (WPW syndrome), ectopic atrial pacemaker from the low right atrium, mannosidosis, Fabry disease and Pompe disease.

Wolff-Parkinson-White Syndrome (Pre-excitation)

It is due to premature conduction of atrial impulses to ventricles through accessory pathways resulting in delta wave and a fusion complex in the ECG (**Fig. 5**). The pre-excitation may be subtle and only detected in the mid precordial leads. The prevalence in children has been estimated to be 0.15–0.3%, higher in those with structural heart disease. Congenital heart diseases with higher prevalence of WPW syndrome are: Ebstein's anomaly of tricuspid

Figure 3 There is right axis deviation of P wave as it is negative in lead I and positive in lead aVF. This is consistent with atrial situs inversus. The chest leads show progressive reduction of the QRS size without the normal progression of R wave, which is suggestive of dextrocardia

Figure 4 Complete heart block: Atrial rate is 110/min and the ventricular rate is 45/min. PR interval is not constant suggestive of AV dissociation

Figure 5 Wolff-Parkinson-White syndrome: Short PR interval is seen. The slurring of initial portion of R wave (delta wave) is seen in all leads, especially V1

valve, congenitally corrected transposition of great arteries, hypertrophic cardiomyopathy and cardiac rhabdomyoma.

Wolff-Parkinson-White syndrome is the most common cause of paroxysmal supraventricular tachycardia (SVT) in children. The incidence of sudden death has been estimated to be as high as 0.5% and cardiac arrest may be the initial presentation. Hence, it is very important to identify this electrical abnormality. Digoxin and verapamil have to be avoided in this condition and beta-blocker therapy is the ideal choice.

QRS Complex

Bundle Branch Blocks

Intraventricular conduction abnormalities due to bundle branch blocks (BBB) are uncommon in normal children. BBB results in wide QRS duration of more than 0.14 sec or more. Right BBB is diagnosed if V1 shows tall wide notched R (rSR' pattern) and the lateral oriented leads (lead I, V5 and V6) show notched wide S wave. In left BBB, the lateral leads show tall notched R wave and V1 shows wide notched QS or rS complex. Right BBB is commonly seen following open-heart surgery.

Right Ventricular Hypertrophy

Many congenital heart diseases are associated with right ventricular hypertrophy. Tall R in V1 ($R/S > 1$), deep S in V6 and upright T wave in right precordial leads indicate the presence of right ventricular hypertrophy. Conditions with pressure overload of right ventricle, e.g., valvar pulmonary stenosis show small q and tall R pattern or only tall R could be seen (**Fig. 6**). Conditions with volume overload of right ventricle, e.g., atrial septal defect shows rSR' pattern.

Left Ventricular Hypertrophy

It produces increased voltages in the left-sided leads and manifest as tall R wave in leads V5, V6 and deep S wave in lead V1 (**Fig. 7**). No definite criteria based on the voltages are available to diagnose ventricular hypertrophy in children. Another important clue for the presence of left ventricular hypertrophy is the presence of T wave abnormalities in leads V5 and V6.

- Tall T waves would indicate underlying volume overloading condition (VSD, PDA).
- ST depression and T inversion in lateral leads could result from pressure overloading of left ventricle (aortic stenosis, coarctation of aorta).

Figure 6 Right ventricular hypertrophy: There is right axis deviation of QRS. Tall R wave, ST depression and T inversion in leads V1-3 is suggestive of right ventricular hypertrophy with pressure overload strain

Figure 7 Left ventricular hypertrophy: Tall QRS complexes in the lateral leads with ST depression and T inversion due to pressure overload of LV

- Peculiarly, neonates with coarctation of aorta have ECG features of right ventricular hypertrophy (and not left ventricular hypertrophy) as the right ventricle receives a greater proportion of systemic venous return from the SVC and faces the systemic vascular resistance in the fetal period through the ductus arteriosus.
- In children with post-tricuspid shunts, large amplitude equiphasic QRS complexes could be seen in the mid precordial leads suggestive of biventricular hypertrophy (Katz-Wachtel phenomenon).

Cardiac Position-Related QRS Changes

In levocardia, the major portion of the ventricles is positioned to the left of the midline with the apex pointing to the left. The

chest leads show a progressive change from a dominant S wave in lead V1 to a dominant R wave in leads V5 and V6. In children with dextrocardia where the major portion of the ventricles is to the right of midline, this normal progression is not seen. Instead, there is progressive reduction in the amplitude of QRS from V2 to V6 (**Fig. 3**). In these children, right-sided leads are commonly taken in the positions corresponding to the left-sided leads that would show *normal* progression of QRS complexes. However, further interpretation of the right-sided leads regarding chamber enlargement is not possible.

ST Segment

ST segment elevation is commonly due to early repolarization as mentioned above. The next common cause is pericarditis.

Other causes are: hyperkalemia, intracranial hemorrhage, pneumothorax or pneumopericardium. Structural anomalies that can cause ST segment elevation are anomalous origin of left coronary artery from pulmonary artery and Kawasaki disease-related coronary arteritis. The former more commonly presents with deep Q waves in leads I, aVL, V5 and V6 with associated T wave inversion. Brugada syndrome is a genetic disorder associated with a high incidence of sudden death due to ventricular fibrillation. ECG in this condition shows ST segment elevation with RBBB pattern in the right precordial leads.

ST segment depression is seen secondary to pressure overload strain. In right ventricular strain, ST depression is seen in right precordial leads while it is seen in left precordial leads in left ventricular strain.

T Wave

In children, T wave is inverted in V1-V3 between 7 days and 7 years. At times, T remains inverted in older children and adolescents (*persistent juvenile T*). As mentioned above, upright T wave in V1 would indicate right ventricular hypertrophy even in the absence of high amplitude R wave.

- T wave inversion in lateral leads represents relative or absolute ischemia and is a feature of ventricular pressure overload strain, anomalous left coronary artery from the pulmonary artery (ALCAPA) and Kawasaki disease with coronary involvement.
- Tall T wave is one of the ECG manifestations of hyperkalemia. Other manifestations of hyperkalemia are disappearance of P wave, broadening of QRS wave, ST segment disappearance resulting in sine wave.
- In hypokalemia, there is gradual reduction in the amplitude of T wave with eventual disappearance of T wave while U wave appears.

DISEASE-SPECIFIC ECG CHANGES

Most of the common congenital heart diseases like tetralogy of Fallot, D-transposition of great arteries, total anomalous pulmonary venous connection, truncus arteriosus, pulmonary atresia, hypoplastic left heart syndrome show Q waves in inferior leads (leads II, III and aVF), RVH and right axis deviation of the QRS

vector, the ECG pattern does not help distinguish one condition from the other. However, absence of above mentioned features point toward some other diagnosis.

Tricuspid Atresia

Q wave in leads I and aVL; left axis deviation of QRS, right atrial enlargement, dominant LV forces in the chest leads (**Fig. 8**).

Common AV Canal Defect

Q wave in leads I and aVL, left axis deviation of QRS, both right ventricular and left ventricular forces are seen (biventricular hypertrophy pattern).

Corrected Transposition of Great Arteries

Normally interventricular septum is depolarized from left to right, that results in Q waves in lateral leads (leads V5 and V6). In this condition, as the ventricles are inverted, the septal depolarization is also reversed. Hence, *q* waves are absent in V5 and V6, but can be seen in right precordial leads (V3R, V1).

Ebstein's Anomaly

Giant P waves, RBBB pattern, low voltage complexes (especially in limb leads). Look for the presence of delta wave, as WPW syndrome is commonly associated. The accessory pathway is usually right sided and hence V1 will show deep S wave (**Fig. 9**).

Pompe's disease This condition produces apparent hypertrophy of the ventricles due to accumulation of glycogen. Short PR interval, very tall QRS complexes in multiple leads (**Fig. 10**).

Dilated Cardiomyopathy

In idiopathic dilated cardiomyopathy, ECG may be normal or show broad QRS complexes in sick patients. However, in any case of cardiomyopathy, two common treatable causes that need to be ruled out are ALCAPA and tachycardiomyopathy. ECG signs of ALCAPA are ST depression and Q waves in lateral leads (leads V5, V6, I and aVL) (**Fig. 11**). Persistent high heart rate should make one to suspect the ongoing tachycardia. Even when the suspicion is small, it is useful to administer adenosine and record the effect on the rhythm.

Figure 8 Tricuspid atresia: Left axis deviation of QRS, Q waves in leads I and aVL and absence of RV forces in right-sided leads

Figure 9 Ebstein's anomaly: Tall P waves due to right atrial enlargement. Broad and bizarre QRS complexes of RBBB morphology typically seen in this condition

Figure 10 Pompe disease: Very tall QRS complexes in all the leads with relatively short PR interval

Pericarditis

ST elevation is seen in almost all the leads with its concavity upward. In addition, there is PR depression (**Fig. 12**).

ARRHYTHMIAS

In any child presenting with tachycardia, it is important to document the rhythm with a 12-lead ECG unless the child is hemodynamically

compromised. It is particularly useful to record the effects of administration of medications such as adenosine because important clues to the underlying arrhythmia are unraveled. SVT is much more common than ventricular tachycardia (VT). QRS complex is narrow and similar to that of sinus rhythm in SVT. If the QRS complex is different from sinus, VT should be diagnosed even if the QRS is relatively narrow. Any wide QRS tachycardia should be considered as VT until proved otherwise.

Figure 11 Anomalous left coronary artery from the pulmonary artery: Note the deep Q waves in leads I, aVL, V5 and V6. These leads also show ST depression and T wave inversion

Figure 12 Pericarditis: ST elevation is seen in almost all the leads with its concavity upward. In addition, there is PR depression

Chapter 40.8

Chest Skiagram in Heart Disease

BRJ Kannan

A systematic approach to interpret chest X-ray (CXR) is quintessential in the management of cardiac illnesses in children. This would entail training one's mind to observe routinely for several diagnostic parameters, a short list of which would include assessment of the following: (1) situs, (2) cardiac position, (3) cardiac/chamber enlargement (4) arch sidedness, (5) lung vasculature, (6) lung parenchyma, (7) bony cage, and (8) diaphragm.

RADIOLOGICAL ASSESSMENT OF THE HEART SHADOW

Situs and Cardiac Position

Situs refers to the location of organs. There are three parameters to assess with respect to this:

1. *Abdomen for visceral situs:* In the abdomen, liver is normally on the right side and stomach on the left. This normal position corresponds to *situs solitus*. This is identified in the CXR by the location of the gas shadow in the gastric fundus.
2. *Chest for visceral situs:* In the chest, location of the three lobed and bilobed lungs corresponds to the organs in the abdomen. The right bronchus is broad, short and takes a vertical course while the left bronchus is narrow, long with a more horizontal lie.
3. *Atria for cardiac situs:* Atrial position corresponds to the position of the organs in the chest and abdomen, i.e., if the liver is on the right side, right lung is trilobed and RA would be on the right side.

Normally, major portion of the ventricles and the apex are located in the left side of the chest and this is termed as *levocardia*. If the apex is seen in the right side of the chest, it is called *dextrocardia*. If the heart takes a vertical position in the center of the chest, it is called as *mesocardia*. It is important to know and remember that the position of the ventricles need not always correspond to that of the atria.

In a situs solitus situation where the RA would be on the right side, ventricles need not always be facing the left, i.e., a child can have dextrocardia even if the situs is solitus. Hence a child could have any of the combinations shown in **Box 1**. If we are not able to clearly define the situs, i.e., midline stomach with ill-defined bronchial shadows, it is termed as situs ambiguous.

Cardiac Chamber Enlargement

The right heart border is formed by superior vena cava (SVC) and RA. The left heart border is formed by aortic knuckle, left atrial (LA)

appendage and left ventricle (LV). Main pulmonary artery lies at the slight concavity between the aortic knuckle and the LA appendage. Apex is formed by the LV. However, these are applicable only to those with situs solitus, levocardia with normal atrioventricular and ventriculoarterial connections.

Normally, cardiothoracic ratio (CTR) is less than 55%. The right heart border is just beyond the right border of thoracic spine. At times, an enlarged ascending aorta, as seen in bicuspid aortic valve, could form the right heart border. Significant shift of the right border would mean enlargement of atria, especially RA. LA dilatation might not produce obvious cardiomegaly. A shadow within shadow (outline of LA would be seen within RA) and more horizontal shift of left bronchus are the signs of LA enlargement in CXR. Heart more commonly enlarges in the left side, usually due to LV dilatation. Greater the dilatation, more would be the downward and outward shift of the cardiac apex. Isolated RV enlargement causes minimal cardiomegaly in the anteroposterior CXR. Upturned apex is a sign of RV enlargement.

Aortic Arch Sidedness

Normally the ascending aorta arches over the left bronchus and descends along the left border of thoracic spine. This arrangement is referred to as left-sided aortic arch. Normal hearts and most of those with CHD will have left aortic arch. If the arch is right sided, it is an important clue for the underlying *conotruncal anomalies*. If the pulmonary blood flow (PBF) is normal or increased, it would suggest truncus arteriosus and if the PBF is reduced, it would suggest tetralogy of Fallot (TOF).

Aortic arch sidedness is usually identified by the prominent aortic knuckle. However, it might not be discernible and could be masked by the thymus shadow in infants. A more consistent sign is to look for the tracheal indentation caused by the arch.

Lung Vasculature

A dilated main PA is easily identified by the prominent round shadow below the aortic knuckle. The right pulmonary artery branch courses horizontally to the right. Hence, this is also easily visible in the CXR if enlarged. The left pulmonary artery branch courses anteroposteriorly. Hence, it is not seen in the anterior posterior projection of the CXR. However, its peripheral branches are visible in the lung fields. Correct exposure and penetration is needed for the proper interpretation of PBF.

The number of end on view appearances to assess the degree of PBF is neither sensitive nor specific. An increased radiolucent (blackish appearing) lung fields would suggest reduced PBF; large central and peripheral branches of PA would suggest increased PBF. Repeated readings of CXRs with various degrees of PBF is the surest way of proper interpretation.

Increased PBF is a feature of left-to-right shunts and admixture lesions like single ventricle. Decreased PBF is seen in TOF, its variants and severe Ebstein's anomaly.

Lung Parenchyma

Pneumonitis and pulmonary congestion/edema are common features of those conditions that cause increased PBF. If the opacity is predominantly located near the hilum, it may be secondary to early pulmonary edema. A more florid pulmonary edema would show opacities distributed in all the lung fields. A uniform ground glass haze is indicative of severe pulmonary venous obstruction and is seen in obstructed (usually infradiaphragmatic) total anomalous pulmonary venous drainage (TAPVD). This will mimic the picture of respiratory distress syndrome and one should always consider the possibility of this surgically correctable cardiac lesion in neonates and infants. Hypoplasia or collapse of

BOX 1 Combinations of visceral, atrial and ventricular situs

Gastric shadow	Left atrium	Cardiac apex	Situs	Cardiac position	Figure
Left	Left	Left	Solitus	Levocardia	1A
Left	Left	Right	Solitus	Dextrocardia	1B
Right	Right	Right	Inversus	Dextrocardia	2B
Right	Right	Left	Inversus	Levocardia	2A

a lobe of lung would result in shift of the cardiac shadow toward that side. It is a consistent feature of Scimitar syndrome where right lower lobe hypoplasia results in shift of the cardiac shadow toward the right.

Bony Cage and Diaphragm

Rib notching (Dock's sign) is a very uncommon feature of coarctation of aorta these days because of early recognition and intervention. It is seen only after 10 years of age due to sclerosis of the ribs secondary to the enlarged intercostal collaterals. Elevated diaphragm, especially in the postoperative setting would mean diaphragmatic paralysis. Eventration of diaphragm also would have the same X-ray picture as that of the diaphragmatic paralysis.

CHEST X-RAY FINDINGS IN SPECIFIC CARDIAC LESIONS

Atrial Septal Defect

Cardiomegaly is usually not a feature. However, if the RV is grossly dilated forming cardiac apex, CTR might be increased. Enlarged right atrial and pulmonary artery shadow are the usual findings. Lung fields show varying degrees of increased PBF. Pulmonary hypertension is not a feature in children. When it occurs in adults, the CXR would show grossly dilated heart and pulmonary arteries.

Ventricular Septal Defect

In the absence of other factors like anemia, cardiomegaly directly correlates with the degree of PBF in all post-tricuspid shunts, which include ventricular septal defect (VSD), aortopulmonary window and patent ductus arteriosus (PDA). Hence, increased CTR is the rule in large defects. Enlarged pulmonary artery and increased PBF are the other findings. If the child develops pulmonary vascular obstructive disease, then the PBF would decrease. This will result in reduction in the LA and LV sizes. Hence, enlarged heart would regress toward normal if the child develops Eisenmenger syndrome. The central pulmonary arteries might still remain dilated. However, the peripheral branches would be reduced in size causing *peripheral pruning* of the pulmonary arteries.

Patent Ductus Arteriosus

In addition to the findings of VSD, ascending aorta and arch could be prominent in large shunts as they too form a part of the left-to-right shunt circuit.

Tetralogy of Fallot

The findings of a classical TOF are absence of cardiomegaly and reduced PBF. Presence of right-sided aortic arch is an important clue. Though *boot-shaped heart* has been traditionally described, it is not consistently seen and is not specific for this diagnosis. Many infants with normal heart too have boot-shaped heart. In pink TOF, the PBF is well-maintained to normal or even higher than normal. Hence, CXR could show mild cardiomegaly with normal to mildly increased PBF.

Transposition of Great Arteries

In the early neonatal period, children have cardiomegaly and increased PBF. The *egg-on-side* appearance could be seen in the CXR. In the late neonatal period or older children, PBF and CTR could be normal. If there are additional defects like VSD or PDA, cardiomegaly and increased PBF persist.

Total Anomalous Pulmonary Venous Drainage

Cardiomegaly is the usual feature. Pulmonary venous hypertension could be noted. In the supracardiac type, *figure-of-eight* appearance has been described. The left superior mediastinal shadow is caused by the vertical vein and dilated SVC causes the corresponding right-sided shadow. However, this finding develops only beyond 3–6 months and should not be relied upon to diagnose this condition, which is a surgical emergency. In obstructed TAPVD (all infradiaphragmatic connections and some of the supracardiac and cardiac types) increased pulmonary venous hypertension causes severe pulmonary edema. This results in ground-glass haze of the lung fields mimicking respiratory distress syndrome.

Figures 1 to 18 depict the common radiological findings in various heart diseases in children.

Figures 1A and B (A) Situs solitus, levocardia. Note the air bubble in the stomach and the bronchial arrangement; (B) There is dextrocardia. However, one should not assume that there is situs inversus. Here too the situs is normal, i.e., solitus

Figures 2A and B (A) The situs is inversus. However, the cardiac shadow is situated more in the left chest with the apex facing left suggestive of dextrocardia. Note that the aortic arch is right sided; (B) Situs inversus with dextrocardia

Figure 3 Right aortic arch. The aortic knuckle and the thoracic aorta are obvious in this X-ray. However, the tracheal indentation caused by the aortic arch is more consistent and useful in most of the situations in locating the sidedness of the arch

Figures 4A to C Various examples of right-sided aortic arch. Tracheal indentation is an important and very useful clue

Figures 5A and B These two X-rays are from children who were ventilated for severe cyanosis. They show markedly reduced pulmonary blood flow. Heart diseases causing reduced pulmonary blood flow should be suspected in any child when the degree of systemic desaturation is disproportionate to the lung parenchymal shadows

Figure 6 Atrial septal defect. Mild cardiomegaly, prominent right atrium and main pulmonary artery shadows are seen

Figure 7 Primary pulmonary hypertension. The findings would mimic atrial septal defect. The main pulmonary artery and branch pulmonary arteries are significantly dilated with minimal or no cardiomegaly

Figure 8 Ventricular septal defect. Cardiomegaly and increased pulmonary blood flow are the findings of a moderate to large defect. Note that the classical description of down and out shifting of apex because of left ventricular dilatation is not always seen in infants

Figure 9 Eisenmenger syndrome. Normal sized heart, prominent hilar pulmonary arteries with pruning of the peripheral vessels

Figure 10 Supracardiac total anomalous pulmonary venous drainage with figure-of-eight appearance

Figures 11A and B Obstructed total anomalous pulmonary venous drainage. Severe pulmonary venous hypertension causes uniform ground glass appearance

Figure 12 Transposition of great arteries. Cardiomegaly and increased pulmonary blood flow are seen. Absence of thymic shadow results in narrow pedicle and the egg-on-side appearance

Figure 13 Pulmonary arteriovenous fistula. In a cyanotic child, absence of cardiomegaly and presence of round shadows in the lungs suggests the possibility of this condition

Figure 14 Ebstein's anomaly. Grossly dilated RA and inflow portion of the RV cause cardiomegaly. Other differential diagnoses for this CXR picture are myocarditis/dilated cardiomyopathy and pericardial effusion

Figures 15A and B Tetralogy of Fallot. (A) Pink TOF. Cardiothoracic ratio and pulmonary blood flow are normal; (B) Cyanotic TOF. Heart size is reduced with blackish lung fields suggestive of severely reduced pulmonary blood flow

Figure 16 Tetralogy of Fallot with absent pulmonary valve syndrome. Cardiothoracic ratio is increased. MPA and branch pulmonary arteries are grossly dilated

Figure 17 Corrected transposition of great arteries. Situs solitus with dextrocardia. Ascending aorta forms the smooth upper superior mediastinal shadow suggestive of L-shaped aorta

Figure 18 Scimitar syndrome. Note the loss of lung volume in the right lower zone with shift of mediastinum toward right. At times, the anomalously draining scimitar vein could be seen as a curved radiopaque shadow to the right of right border of heart

Chapter 40.9

Echocardiography

Balu Vaidyanathan

FETAL ECHOCARDIOGRAPHY

The availability of fetal echocardiography has provided a unique opportunity to diagnose and understand various forms of congenital heart disease (CHD) from very early gestation. Prenatal diagnosis offers a much wider option for the management of CHD to the expectant family, especially in the setting of limited resource environments.

Indications, Timing and Technique of Fetal Echocardiography

A basic screening of the fetal heart needs to be done in all pregnancies as a part of the mid-trimester anomaly detection scans. A detailed fetal echocardiographic evaluation is indicated in high-risk pregnancies with a greater probability of CHD (Table 1). The optimal timing for fetal echocardiography is between 16 weeks and 20 weeks gestation.

Various clinical societies have their detailed guidelines for conducting fetal echocardiography. This includes evaluation of the fetal lie and position, abdominal situs, four-chamber view, outflow tracts, the three-vessel view, the bicaval view and the evaluation of the ductal and aortic arches. A fetal Doppler evaluation for cardiac rhythm and function completes the study. For the purpose of screening, a combination of four-chamber view and outflow tracts will be adequate to detect most major forms of CHD.

Figures 1 to 3 illustrate the standard views for fetal echocardiography and the common abnormalities detected using these views.

Table 1 Indications for fetal echocardiography

Fetal	Maternal	Familial
1. CHD suspected on screening scans	1. Maternal CHD	1. Previous child with CHD
2. Extracardiac anomalies	2. Teratogen exposure	2. Paternal CHD
3. Chromosomal anomalies	3. Metabolic disorders—Diabetes mellitus	3. Mendelian syndromes
4. Increased first trimester nuchal fold thickness	4. Maternal autoimmune disease	
5. Nonimmune hydrops	5. Intrauterine infections	
6. Irregular heart beat		
7. <i>In vitro</i> fertilization/Intracytoplasmic sperm injection		

Abbreviation: CHD, congenital heart disease.

Impact of Prenatal Diagnosis on Management of CHD

The potential impact of prenatal diagnosis on outcomes of fetal CHD depends upon several factors like the complexity of CHD, long-term outcomes after treatment, presence of associated anomalies, psychosocial and economic factors as well as local rules and regulations regarding pregnancy termination. In summary, the following options are available to the family after the diagnosis of fetal CHD:

1. *Termination of pregnancy*: An option to be considered and discussed with parents in accordance with the local and regional laws after detection of very complex CHD where only palliative forms of surgery can be offered with guarded or variable long-term outcomes and compromised quality of life.

Figures 1A and B Four-chamber view of fetal heart. Panel A shows a normal four-chamber view of the fetal heart. Note the symmetry of the cardiac chambers. Descending aorta (DA) seen between the left atrium and the spine (S). The arrow points to the patent foramen ovale. Panel B shows a fetal heart with hypoplastic left heart syndrome. The left ventricle (LV) is hypoplastic and the apex of the heart is formed by the right ventricle (RV). The atrial septum (arrow) is bulging toward the right suggesting that the foramen ovale is restrictive or closed

Figures 2A to C Fetal echo: evaluation of outflows. Panel A shows the left ventricular outflow tract (arrow) coursing from the left side toward the right. Panel B shows the direction of the right ventricular outflow tract (bold arrow) coursing from the right of the fetus toward the left and spine (S). The bifurcation of the outflow tract is clearly seen (small arrows). Note that the outflow tracts thus cross each other. Panel C shows the characteristic absence of crossing of outflows with parallel outflow tracts in transposition of the great vessels. The pulmonary artery (PA) is seen arising from the left ventricle while the aorta (Ao) originates from the anterior right ventricle

Figures 3A to C Fetal echo: three-vessel view. Panel A shows a normal three-vessel view with equal sizes of the aorta (Ao) and the pulmonary artery (PA). Panel B shows a relatively small Aorta vis-à-vis pulmonary artery. Panel C shows the significant narrowing of the aorta (black arrow) at the level of Isthmus (I). The arterial duct is also shown (D). Panel B and C characterize the typical findings in fetal coarctation of aorta

2. *Planned delivery and perinatal cardiac care:* This is applicable for CHDs that are potentially lethal in the neonatal period without appropriate specialist intervention and treatment (e.g., transposition of the great arteries, other ductus dependent conditions) which offers a possibility of favorable long-term outcomes with reasonable quality of life.
3. *Transplacental therapy:* This is offered for fetuses with tachyarrhythmia and bradyarrhythmias including complete heart block with excellent results in current era.
4. *Fetal interventions:* At present the scope of fetal cardiac interventions is limited to obstructive lesions of outflow tracts, especially aortic stenosis.

ECHOCARDIOGRAPHY IN THE NEONATE

The definitive diagnosis of CHD at the bedside is feasible by echocardiography. Besides a detailed anatomic evaluation of CHD, echocardiography also permits comprehensive *functional and hemodynamic evaluation* of the heart such as degree or severity of obstructions, regurgitations, contractility besides cardiac output. Indications for neonatal echocardiography are listed in **Box 1**.

Protocol for Neonatal Echocardiography

A sequential chamber analysis using a combination of echocardiographic views is recommended. A broad guideline only is

BOX 1 Indications for neonatal echocardiography

- Whenever CHD is suspected based on clinical evaluation (presence of cardiac murmur, cyanosis, discrepant pulses or any unexplained circulatory failure and shock)
- Failed routine neonatal pulse oximetry screening test
- All those with genetic syndromes or extracardiac anomalies commonly associated with CHD (e.g., Trisomy 21, 22q deletion syndrome, VACTERL association, etc.).

given and for detailed protocol for echocardiography the interested reader may refer to the suggested references. The following steps are used to identify:

1. The liver and splenic positions in the abdomen and atrial situs and atrial arrangement.
2. Ventricular morphology and atrioventricular connection (concordance).
3. Identification of great vessels and ventriculoarterial concordance.
4. Associated abnormalities and assessment of their severity.

The following views or windows are commonly employed to gather information during echocardiographic evaluation: (1) subxiphoid: (i) long and (ii) short axis views; (2) four-chamber view; (3) parasternal, (i) long and (ii) short axis views; (4) ductal view (high parasternal short axis view); and (5) suprasternal view.

Figures 4A to E Subxiphoid view evaluation. Panel A shows the position of the transducer in subxiphoid view evaluation. Note that the transducer is held vertical with pointer facing toward the feet of the patient. Panels B to E show various structures seen on sweeping the transducer from right to left on subxiphoid short axis sweep. Starting from atria, atrial septum and systemic veins (Panel B), one can visualize the various components of the ventricular septum from membranous (Panel C, bold arrow), infundibular (Panel D) and apical (Panel E)

Abbreviations: RA, right atrium; LA, left atrium; SVC, superior vena cava; IVC, inferior vena cava; RPA, right pulmonary artery; RV, right ventricle; LV, left ventricle; RVOT, right ventricular outflow tract; PA, pulmonary artery.

Figures 5A to D Four-chamber view. Panel A shows the position of the transducer in this view. The transducer is placed in the cardiac apex with pointer facing to the left. Sweeps are made in the anteroposterior plane to visualize the cardiac chambers and valves (Panel B), coronary sinus by caudal tilt (Panel C, arrow) and left ventricular outflow tract by cranial tilt (panel D)

Abbreviations: RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; CS, coronary sinus; Ao, aorta.

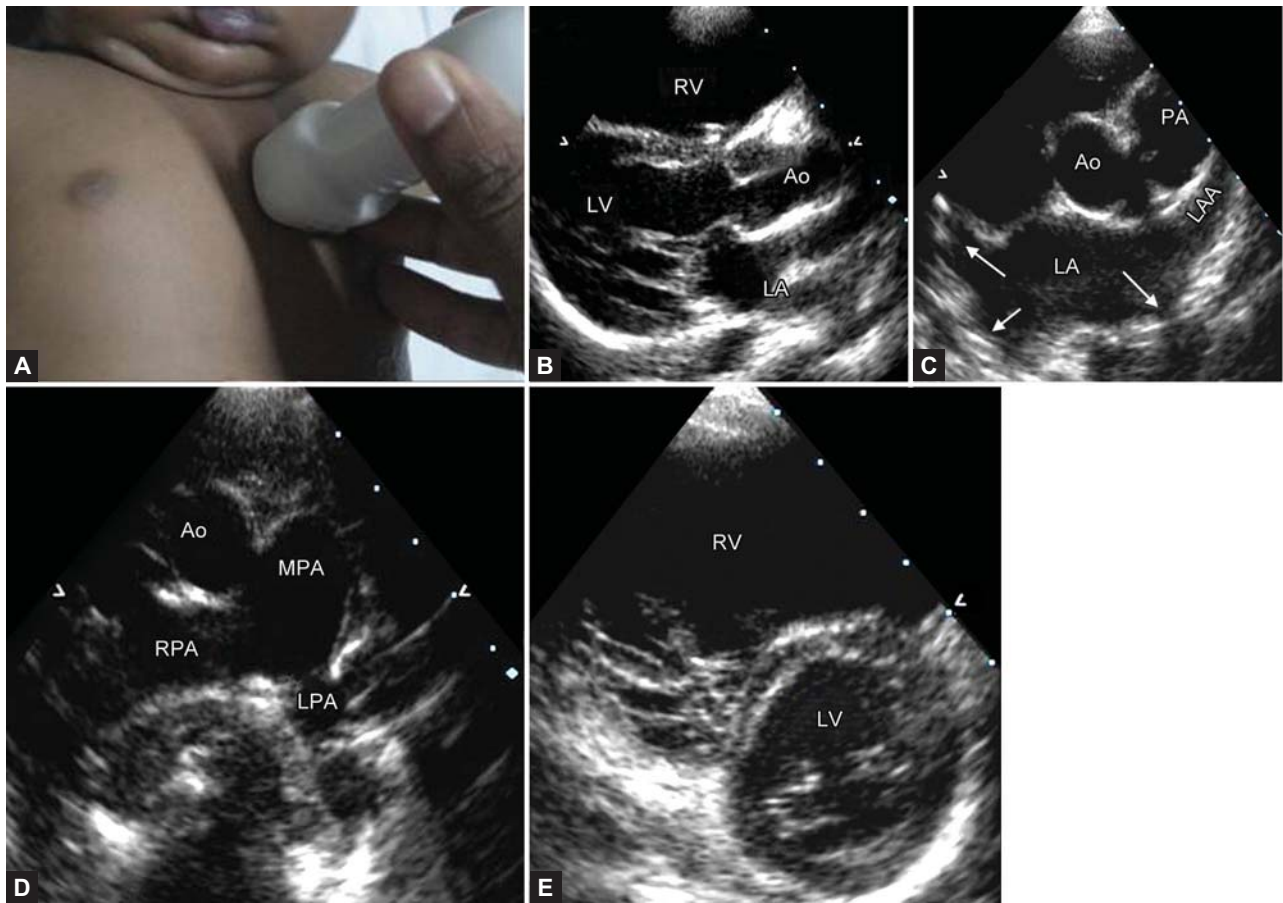

- In the subcostal approach, various structures are imaged by sweeping the transducer in the cephalocaudal plane (long axis) or right to left sweep in short axis,
- The subxiphoid views permit detailed evaluation of situs, position of heart and its connections, atrial and ventricular septum and atrioventricular valves,
- The four-chamber and the parasternal views provide additional information about ventricular function, valves and outflows,
- The ductal view (high parasternal short axis view) for the PDA, and
- Suprasternal view for the evaluation of aortic arch.

In a sick neonate, the echocardiographic evaluation may have to be limited to the most essential views taking care that the hemodynamic status of the patient is not compromised during the study (especially suprasternal views in a ventilated neonate). **Figures 4 to 8** illustrate the common echocardiographic views and the corresponding images of the heart obtained in each view.

Standard principles for image optimization, Doppler evaluation and measurements need to be followed.

Functional Echocardiography

This approach utilizes a combination of two-dimensional and M-Mode imaging and Doppler (continuous wave, pulse wave

Figures 6A to E Parasternal views. Panel A shows the position of transducer in these views. In the parasternal long axis view, the transducer is placed along the left side of sternum with pointer facing toward right shoulder. Rotating the transducer through 90° with pointer facing left shoulder gives the short axis view. Panel B shows the parasternal long axis image of the heart showing the left ventricular outflow tract, mitral valve and left atrium. Panel C is a short axis view of the semilunar valves and coronaries. The left atrium with the pulmonary veins (arrows) and appendage are seen posterior to aorta. Panel D is a short axis view showing the bifurcation of the pulmonary arteries. Panel E shows a short axis view of the left ventricle and mitral valve obtained by tilting the transducer caudally

Abbreviations: LA, left atrium; Ao, aorta; RV, right ventricle; LV, left ventricle; PA, pulmonary artery; LAA, left atrial appendage; MPA, RPA, LPA, main, right and left pulmonary artery.

Figures 7A and B High parasternal (ductal) view. This view is obtained by keeping the transducer in the first left intercostal space with transducer facing cranially. Panel A shows the anatomy of the patent ductus arteriosus (PDA). The arrows indicate the pulmonary end of the PDA, which is typically the narrowest portion. The diameter of the PDA is measured at this level. The duct ampulla is well profiled. Panel B shows color Doppler flow evaluation of the PDA with a left-to-right flow

Abbreviations: MPA, main pulmonary artery; LPA, left pulmonary artery.

Figures 8A and B Suprasternal view. This is obtained by keeping the transducer in the suprasternal notch. Panel A shows the long-axis image imaging the aortic arch and its branches. Panel B shows a short axis suprasternal view by rotating the transducer to the right by 90°. This view is excellent for imaging the superior vena cava and its innominate connection and the pulmonary arteries. A caudal tilt from this position shows the left atrium with all the pulmonary veins draining into it (arrows, Crab view)

Abbreviations: LCC, left common carotid; LSC, left subclavian; Inn, innominate vein; RPA, right pulmonary artery; LA, left atrium; Ao, aorta; Is, Isthmus; DA, descending aorta.

and color) for the evaluation of cardiac function. Evaluation of cardiac output is feasible through measurement of either left or right ventricular outputs or by superior vena cava (SVC) flow. Functional echocardiography is extremely valuable in hemodynamic assessment of PDA and its significance; evaluation of pulmonary artery pressures and RV function in infants with persistent pulmonary hypertension of the newborn (PPHN); and evaluation of shock states in neonates and infants.

Pitfalls, Limitations and Lesions often Overlooked

Echocardiography is a subjective tool and the quality of the study is influenced by several factors. Equipment quality and expertise of the echocardiographer are primary determinants of accuracy in reporting. The patient related factors and echo windows significantly affect the study. In very sick neonates on ventilator, echo windows maybe suboptimal due to hyperinflated lungs and the study may have to be truncated to get basic information.

Some of the common critical CHDs that are often overlooked include anomalous pulmonary venous connections, coarctation of aorta and coronary anomalies. Clues for anomalous pulmonary venous connections include significant enlargement of right-sided chambers, relatively small left atrium, severe pulmonary hypertension and an atrial level communication shunting exclusively right-to-left. In such cases, a careful search for the common pulmonary vein chamber and its drainage site is required. Exclusion of coarctation is mandatory in any neonate with unexplained shock and this is feasible through a thorough evaluation of the aortic arch using the suprasternal view. In young infants with left ventricular dysfunction, coronary anomalies like anomalous left coronary artery from the pulmonary artery (ALCAPA) must be carefully looked for. Presence of wall motion abnormalities and scarred papillary muscles should prompt a very close evaluation with color Doppler of the coronaries using the parasternal short axis view.

IN A NUTSHELL

1. Echocardiography is the gold standard for bedside diagnosis of CHD.
2. Prenatal diagnosis of CHD is feasible using antenatal ultrasound screening; basic evaluation includes the four-chamber view, outflow tracts and the three-vessel view.
3. Prenatal diagnosis can significantly impact the management of severe forms of CHD in the current era.
4. Bedside echocardiography is the definitive method to exclude CHD in the newborn baby.
5. A standard protocol for evaluation the heart in a segmental manner needs to be followed for the conduct of echocardiography.
6. Functional echocardiography permits a detailed evaluation of the underlying hemodynamic status and this can have a significant impact on management of a sick neonate in the NICU (especially in treatment of PDA in the preterm infant).
7. Clinicians performing echocardiography in the neonate needs to be aware of the pitfalls and the common lesions which may be overlooked.
8. Recent data on neonatologists performing echocardiography have shown high sensitivity and specificity for detection of CHD and cardiac functional assessment.
9. Echocardiography has the potential to significantly impact early diagnosis of CHD and hemodynamic monitoring of sick infants in the NICU in the near future.
10. There is a pressing need for formal training and accreditation programs in neonatologist performed echocardiography, in collaboration with pediatric cardiologists.

Chapter 40.10

Cardiac Catheterization

Duraisamy Balaguru

Cardiac catheterization is an invasive modality where small catheters are inserted via vein and artery respectively to obtain direct pressure and oxygen saturation measurement. Injection of radiologic contrast dye provides angiograms for anatomic and flow details. From the oxygen saturation and pressure measurements, various calculations can be made including cardiac output, estimates of pulmonary blood flow and vascular resistance, intracardiac shunts and valve area. Technologic advances including balloon catheters, stents, occlusion devices and valves enable transcatheter treatment of cardiovascular defects. Recent developments enable three-dimensional construction of images from rotational angiography. Cardiac magnetic resonance imaging (MRI) and computed tomography (CT) scans provide alternative noninvasive methods of imaging to aid diagnosis and management of congenital heart disease in children.

CARDIAC CATHETERIZATION

Indications

- Diagnosis of cardiac and extracardiac vascular defects by angiography and assessment of cardiac function by measurement of cardiac output, intracardiac shunts, pulmonary vascular resistances and valve area.
- Pulmonary vasoreactivity testing in patients with pulmonary hypertension with or without congenital heart defects.
- Transcatheter treatment of cardiac and extracardiac defects—balloon atrial septostomy, balloon valvuloplasty, balloon angioplasties, stent therapy, closure of congenital heart defects and transcatheter valve placements. Transcatheter therapy has become first-line management in suitable patients for the following conditions: Valvar stenosis [pulmonary stenosis, aortic stenosis (PS, AS)], coarctation, patent ductus arteriosus (PDA), atrial septal defect (ASD), ventricular septal defect (VSD) and extracardiac collateral vessels. These procedures are briefly reviewed below.

Even though indications for cardiac catheterization for diagnostic purpose only have diminished since the advent of echocardiography, cardiac MRI and CT scans, approximately 40–45% of the procedures in a catheterization laboratory constitute diagnostic catheterizations.

Vascular Access

Establishing access to the vascular system—venous, arterial or both—is the first step in cardiac catheterization. Standard approach for children includes percutaneous Seldinger technique via femoral vein and femoral artery. Additional options for venous access include umbilical vein in neonates, subclavian and internal jugular veins in all age groups. Additional options for arterial access include umbilical artery in neonates. Radial, brachial, axillary and carotid artery may be used in other age groups under special circumstances. Carotid artery access is obtained usually by a surgical cut-down procedure. Vascular access may be difficult in patients with small or stenotic vessels from prior catheterizations, additional guidance with Doppler or ultrasonography may increase the success of obtaining vascular access.

TRANSCATHETER TREATMENT

Balloon Atrial Septostomy

Balloon atrial septostomy is performed in newborns or infants, to enlarge the atrial level communication between right and left atria. A balloon catheter is introduced from the femoral or umbilical vein, advanced across patent foramen ovale (PFO) to left atrium (LA). The balloon is then inflated in LA (**Fig. 1**) and pulled across the PFO to right atrium, creating a larger atrial level opening. Indication for this procedure includes (i) dextrotransposition of great arteries in a newborn who has inadequate mixing, (ii) decompression of right atrium in tricuspid atresia and (iii) decompression of left atrium in mitral atresia and related disorders. This procedure is highly effective in newborns. But, may be more difficult in older infants due to thickening of the atrial septum with age where blade atrial septostomy or static-balloon atrial septoplasty is performed with or without stent placement.

Balloon Valvuloplasty

Isolated, moderate to severe pulmonary or aortic valve stenosis is the common indication for this procedure in children. Congenital mitral stenosis and tricuspid stenosis requiring balloon valvuloplasty are rare. Rheumatic mitral stenosis is amenable to this procedure as well. However, significant rheumatic mitral stenosis is more common in adolescents and adults than young children. Presence of moderate or severe valvar regurgitation is a contraindication for the procedure.

Procedure involves placing an appropriate size balloon across the stenotic valve and inflating to a 2–4 atmospheric pressures until the waist in the balloon is obliterated. Results of balloon pulmonary valvuloplasty (**Fig. 2**) are excellent with low recurrence rate. Pulmonary regurgitation induced by balloon procedure is minimal and well tolerated. On the contrary, balloon aortic valvuloplasty (**Fig. 3**) has relatively poorer results with higher rate of recurrence. Aortic regurgitation induced by balloon procedure may be poorly tolerated especially if it is severe. For isolated pulmonary stenosis and aortic stenosis, balloon valvuloplasty is considered the first choice of treatment.

Figure 1 Balloon atrial septostomy in a newborn. Image shows Rashkind's septostomy catheter is inflated in the left atrium using dilute contrast. This balloon will be pulled across the patent foramen ovale using fluoroscopy and echocardiographic guidance (Echo transducer is held by a technician at the chest to provide additional guidance during the procedure). Umbilical venous access was used in this 1-day-old newborn with transposition of great arteries

Balloon Angioplasty and Stents

Coarctation of aorta (except during infancy) (**Figs 4 and 5**) and pulmonary artery stenosis (**Figs 6A to C**) are indications. Balloon angioplasty can also be applied to stenosis of other vessels such as superior vena cava (SVC), inferior vena cava (IVC) and surgical conduits. These procedures have been highly successful with technologic developments in balloon design. Restenosis develops in approximately ~30% of children who undergo successful balloon angioplasty. Placement of stents prevents or reduces the restenosis rate. However, since currently-available stents do not grow with the child, stent placement is limited to older children or to children with surgical conduits that are planned for replacement at a future surgery. Balloon angioplasty and stent procedures have helped to prolong the longevity of surgically placed conduits.

Patent Ductus Arteriosus Closure

Transcatheter closure is the first-line therapy for PDA. Various devices including Gianturco coils (**Figs 7A and B**), and Amplatzer

duct occluders (St Jude Medical, Minneapolis, MN, USA) and Nit-Occlud device (PFM medical, Koln, Germany) are some of the transcatheter device options. Excellent results are achieved using transcatheter closure of PDA. Transcatheter technique is not suitable for preterm babies and small infants at this time, though this is evolving. When transcatheter technique is not suitable either due to PDA size/anatomy or patient size, surgical ligation is the option. Surgical ligation is performed either by thoracotomy or using thoracoscope (Video-assisted thoracoscopic surgery). Video-assisted thoracoscopic surgery for PDA closure is available in some centers for children of all sizes, including premature infants down to 600 g.

Atrial Septal Defect Closure

Only secundum type ASD that is centrally-placed with adequate rim of tissue around the defect is suitable for transcatheter device closure. Primum ASD and sinus venosus type ASDs need surgical repair when closure is indicated. Several transcatheter ASD

Figure 2 Balloon pulmonary valvuloplasty. Still image during balloon inflation showing the waist in the balloon at the level of pulmonary valve. This waist will be obliterated with full inflation of the balloon. 10 mm calibration marker is on the skin over left chest. Femoral venous access is used for the procedure

Figure 3 Balloon aortic valvuloplasty in a newborn with critical aortic stenosis. Still frame during balloon inflation across the aortic valve. Waist in the balloon is at the level of stenotic aortic valve. Catheter is advanced from femoral artery over a guidewire whose tip is curled up in left ventricle (LV). Umbilical venous line is used for infusions

Figures 4A to C Balloon angioplasty of coarctation. Panel A—Aortic root angiogram shows coarctation (Coarct); Panel B shows balloon inflated across the coarctation segment and Panel C shows good improvement in diameter of the coarctation segment

Figures 5A and B Stent angioplasty of coarctation of aorta in a teenager. Panel A shows PA view of aortogram with a discrete coarctation; Panel B shows the same segment with significant increase in size after stent placement

Figures 6A to C Lateral view images of MPA angiograms illustrating stent placement for left pulmonary artery (LPA) stenosis in a 4-year-old girl after tetralogy of Fallot repair. Panel A shows severe stenosis of origin of LPA; Panel B shows the inflation of balloon with stent mounted on it and Panel C shows MPA angiogram after stent placement. Now, LPA origin is widely open
Abbreviations: MPA, main pulmonary artery; LPA, left pulmonary artery; RPA, right pulmonary artery.

Figures 7A and B Still frames of lateral view of aortic arch (AA) angiograms. Panel A shows a small patent ductus arteriosus (PDA) before closure and Panel B shows a coil delivered by catheterization, occluding the patent ductus arteriosus. No residual shunt is noted

devices are available. Amplatzer septal occluder (St Jude Medical) and Helex® device (WL Gore, Flagstaff, Arizona, AZ, USA) are the popular devices. There are several other devices under development or in clinical trials. In principle, all ASD devices have a waist connecting the two discs. The device is collapsed and loaded into the delivery catheter. The device expands upon delivery inside the heart. The waist portion is placed in the ASD, with the two discs holding the device in place after release. Chest X-ray of a patient with Amplatzer septal occluder is shown in **Figures 8A and B**. Patient selection is important for successful device closure and in preventing complications after device placement. Residual defects occurs after the procedure; majority of them spontaneously close 6 months to 1 year after the procedure.

Ventricular Septal Defect Closure

There are several types of VSDs. Muscular type VSD located sufficiently away from nearby valves is amenable to transcatheter device closure. **Figures 9A and B** shows chest X-ray of an infant who underwent closure of apical muscular VSD using Amplatzer muscular VSD device. Device for membranous VSD closure is in clinical trial at this time. VSD devices are designed similar to ASD devices with wider waist to accommodate for thicker ventricular septum. These are delivered either from femoral venous access or internal jugular venous access. When percutaneous approach is difficult, this procedure is performed by a hybrid approach where a sternotomy is performed and the device is placed through a delivery sheath inserted through the RV free wall of the beating

Figures 8A and B Chest X-ray in PA and lateral views in a patient who underwent transcatheter closure of ASD using Amplatzer septal occluder (black arrows). Device is easier to appreciate in lateral view (Panel B) where the two discs and central waist are recognizable
Abbreviation: ASD, atrial septal defect.

Figures 9A and B Chest X-ray images of a 2-year-old girl who underwent transcatheter closure of apical ventricular septal defect and atrial septal defect using respective Amplatzer devices
Abbreviations: ASD, atrial septal defect; VSD, ventricular septal device.

heart. Hybrid approach avoids an open heart surgery and is a preferred method for small infants in whom percutaneous approach is riskier due to higher incidence of myocardial perforation.

Transcatheter Valve Implantation

Transcatheter pulmonary valve implantation is performed in patients who have undergone prior cardiac surgery for tetralogy of Fallot, pulmonary atresia (PA) or double outlet right ventricle (DORV) with placement of right ventricle (RV)-PA conduit. Current commercially available valve (Melody® Valve; Medtronic Inc. Minneapolis, MN, USA) is a bovine jugular venous valve sutured inside a stent. The stent is then, mounted on a balloon and deployed in RV-PA conduit in pulmonary valve position. Native pulmonary valve annulus is considered unsuitable for transcatheter valve implantation at this time. Transcatheter aortic valve implantations are being performed under clinical trials for elderly adults with aortic stenosis. These transcatheter aortic valves are not suitable for children at this time.

OTHER ADVANCED IMAGING METHODS

Cardiac Magnetic Resonance Imaging

Cardiac MRI is uniquely suited for certain indications such as pulmonary venous return, vascular ring and related anomalies, aortic arch and its branches and similar lesions when they are difficult to define using echocardiography. Intracardiac anatomy is obtained with good tissue characterization (e.g., tumors) and reproducible volume measures, flow characteristics and flow measurements. For example, patients are followed after repair of tetralogy of Fallot with serial MRI at 3–5-year intervals, to measure RV and pulmonary regurgitation volume to determine optimal time for pulmonary valve implantation. **Figures 10A and B** show axial images of a teenager after tetralogy of Fallot repair and mild right ventricular dilatation. Contrast enhanced MRI using Gadolinium provide MR angiography providing functional anatomy, myocardial viability, inflammation and estimation of iron stores. **Figures 11A to C** show a three-dimensional reconstruction of a double-aortic arch.

Limitations of cardiac MRI include lack of widespread availability of the facility or expertise to perform the imaging, need for sedation or general anesthesia in infants and children, prolonged scan times (may exceed 1–2 hours) in sick children and incompatibility of ferromagnetic prosthetic implants in or around the heart such as pacemakers.

Cardiac Computed Tomography

Cardiac CT provides images comparable to cardiac MRI and provides ability to perform three-dimensional reconstructions (**Fig. 12**). However, cardiac CT requires contrast injection to delineate cardiac chambers and blood vessels. Furthermore, cardiac CT uses X-ray causing radiation exposure to the patient. Advantages over cardiac MRI are that acquisition of images is much faster taking a few minutes and when there are ferromagnetic prosthetic implants in the patient. Timing of contrast injection and image acquisition is important. Additional advantage is ability to reconstruct noncardiac structures that will have significant implications in managing the patients. **Figures 13A and B** show images from a 10-month-old child with anomalous origin of left pulmonary artery from right pulmonary artery (the so-called pulmonary artery sling). In this condition, usually there are associated tracheal and bronchial abnormalities as shown by accessory right bronchus originating from the left bronchus.

Figures 10A and B Axial views of the cardiac chambers obtained by MRI. Note panel A has *black-blood* (spin-echo) images while panel B has *bright-blood* (gradient-echo) images. Bright blood images also provide functional assessment

Cardiac CT is best suited for definition of anatomy of vascular structures in the chest and to appreciate their relationship to the surrounding nonvascular structures as in cases of vascular anomalies.

IN A NUTSHELL

1. Technologic advances in cardiac imaging have widened the choice for clinicians to choose the most suitable and least invasive modality based on the clinical condition of the child.

Chapter 40.11

Cardiac Malpositions

P Syamasundar Rao

Cardiac malpositions are usually associated complex congenital heart defects (CHDs). This chapter presents an orderly, methodical and systematic approach to a patient with cardiac malposition. A brief discussion of heterotaxy syndromes will follow.

DEFINITIONS AND TERMINOLOGY

Normal position of the heart is in the left side of the chest (**Fig. 1**) and is expressed as *levocardia*. On the other hand, if the heart is in the right side of the chest (**Fig. 2**), it is described as *dextrocardia*.

Figure 1 Normal position of the heart in the left side of the chest, also described as *levocardia*. The heart is shown on the left side of the chest. The liver (Liv) is on the right and the stomach (Sto) air bubble in left side of the abdomen indicating situs solitus. The trachea (Tr) is in the middle. Abbreviation: UVC, umbilical venous catheter.

Or, it may be in the middle of the chest (**Fig. 3**) when it is called *mesocardia*. Some cardiologists use the position of the apex of the heart to make this determination, but apicality of the heart cannot always be determined with certainty; more importantly, such determination is not necessary for the diagnostic approach to be described here. The heart may be pushed (**Figs 4 and 5**) or pulled to the right (**Fig. 6**); in such situation is called *dextroposition*. Other common terms are defined in **Box 1**.

BOX 1 Cardiac position terminology

- *Situs solitus*: Normal position of the viscera with the liver on the right side and the stomach on the left (**Figs 1 and 2**)
- *Situs inversus*: Left-to-right reversal of the viscera with the stomach on the right and liver on the left (**Figs 7 and 8**)
- *Situs inversus totalis*: Dextrocardia with situs inversus (**Figs 7 and 8**)
- *Isolated dextrocardia*: Dextrocardia with situs solitus (**Figs 2 and 9**)
- *Isolated levocardia*: Levocardia with situs inversus (**Fig. 10**).

Figure 2 Chest X-rays of a child with dextrocardia; the heart in the right side of the chest. The liver (Liv) on the right and the stomach air bubble (Sto) in left side of the abdomen are indicating situs solitus. This is picture of isolated dextrocardia. The trachea (Tr) is in the middle. The sternal and pacemaker wires are related to prior surgery

Figures 3A and B Chest X-rays of two children with the heart in the middle of chest, described as *mesocardia*. The liver is seen across the abdomen without air in the stomach, making it difficult to ascertain atrial situs

Figure 4 Chest X-ray of a baby with dextroposition of the heart (Hrt) secondary to diaphragmatic hernia on the left. The abdominal (Abd) contents including intestines are in the left chest and pushing the heart into the right chest. Note displacement of the trachea (Tr) to the right

Figure 5 Chest X-ray of an infant with dextroposition of the heart (Hrt) due to pneumothorax (Pne) in the left chest pushing the heart into the right chest. Collapsed lung (CoLu) is shown. Note displacement of the trachea (Tr) to the right

EPIDEMIOLOGY

The heart is usually structurally normal in dextroposition. However, in dextrocardia, the prevalence of CHD is higher and the prevalence varies with the associated viscerotransposition. In situs inversus totalis, CHD is present in 3–10% of the babies while in isolated dextrocardia and isolated levocardia, CHD is present in almost 100% of the patients. This is in contradistinction to less than 1% CHD prevalence in normal population.

CARDIAC MALPOSITION: SEGMENTAL ANALYSIS

After dextroposition is eliminated, the cardiac malposition is evaluated by systematic segmental analysis. The approach is similar irrespective of levocardia, dextrocardia or mesocardia. Following exclusion of dextroposition and it is decided that the location of heart in the chest is intrinsic or primary (i.e., innate cardiac malposition), the following issues should be tackled:

1. What is the viscerotransposition?
2. *Ventricular relationship*: Are there two ventricles or one? If two, where are the ventricles located in relation to each other?
3. What is the status of atrioventricular (AV) connections?
4. How are the great arteries related to each other and with ventricles?
5. What is the conotruncal relationship?

1. Viscerotransposition

This may be situs solitus, situs inversus or situs ambiguus (symmetricus or indeterminatus). There are different ways by which the situs may be determined.

P waves in electrocardiogram (ECG) The cardiac impulse usually arises in the sinoatrial node which is located at the superior vena cava-right atrial junction and is transmitted inferiorly and to the left. The ensuing atrial depolarization produces P waves in the ECG. The P wave axis is 45° (Fig. 11) with positive P waves in leads I and AVF (Fig. 12). This is indicative of situs solitus with the right atrium on the right side. The atria are inverted in situs inversus and consequently, the P wave axis will be around 135° (Fig. 11) giving negative P wave in lead I and positive P wave in lead AVF (Fig. 13). If the P wave axis is -45° (Fig. 11), P waves in lead I are positive and

Figure 6 Chest X-ray of a child with dextroposition of the heart due to Scimitar syndrome. The heart is pulled to the right because of hypoplasia of the right lung. Anomalous pulmonary vein is shown (arrow, APV); the name of the syndrome is derived from this vessel because of its shape (Scimitar). Also note the displacement of the trachea (Tr) to the right

Abbreviations: Liv, liver; Sto, stomach.

P waves in lead AVF are negative (Fig. 14) and is called coronary sinus rhythm. Such P wave axis is not helpful in situs localization. Nevertheless, as reviewed latter, coronary sinus rhythm is often present in persistent left superior vena cava and infrahepatic interruption of inferior vena cava (IVC), which are frequently seen in asplenia/polysplenia syndromes.

Viscerotransposition concordance The universal tenet of viscerotransposition concordance suggests that right-sided liver and left-sided stomach (Figs 1, 2 and 9) are associated with morphologic right atrium on the right side and morphologic left atrium on the left side, i.e., situs solitus. On the converse, left-sided liver and right-sided stomach (Figs 7, 8 and 10) are indicative that morphologic right atrium is on the left side and morphologic left atrium on the right side, i.e., situs inversus. Similar sized hepatic lobes on both sides or a midline liver (Fig. 15), irrespective of the position of the stomach suggests

Figure 7 Chest X-ray of a neonate with dextrocardia. The heart (Hrt) is on the right side without displacement of trachea (Tr). The air in the stomach (Sto) is faintly seen on the right and the liver (Liv) on the left side of the abdomen; these findings suggest situs inversus. In addition, the position of the stomach on the right is confirmed by the position of the nasogastric tube (NGT). Since there is dextrocardia along with situs inversus, it is situs inversus totalis

Figure 8 Chest X-ray of an infant with dextrocardia and situs inversus, i.e., situs inversus totalis. No displacement of trachea (Tr) is seen
Abbreviations: Hrt, heart; Liv, liver; Sto, stomach.

that situs ambiguous may be present and asplenia/polysplenia syndromes are likely. Visceroatrial concordance appears to be more consistent than P wave axis in ECG in appropriately identifying atrial situs.

Tracheobronchial tree pattern In normal children with situs solitus, the right bronchus is short and wide and descends steeply whereas the left bronchus is long and narrow and descends more horizontally (**Figs 16A and 17**). In individuals with situs inversus, the tracheobronchial tree pattern is reversed (**Figs 16B and 18**). This method appears to be more precise than the two above described methods. If both bronchi have morphologic appearance of right bronchus (**Fig. 19A**), asplenia syndrome should be considered and if morphologic appearance is that of left bronchus on both sides (**Fig. 19B**), polysplenia syndrome is likely. Exception to these rules can occur but rare.

Figure 9 Chest X-ray of a neonate with isolated dextrocardia; i.e., dextrocardia with situs solitus with the liver (Liv) on the right and the stomach (Sto) on the left. No displacement of trachea (Tr) is seen

Vena cava-aorta relationship A constant relationship between the IVC and aorta (Ao) exists at the level of diaphragm; this may be visualized by short axis echocardiographic views (**Fig. 20A**). The vessels may be identified by their sizes (IVC larger than Ao), direction of flow (towards the heart for IVC and away from the heart for the Ao) and pulse wave characteristics (**Figs 20B and C**). In situs solitus (normal), the IVC is to the right of the spine and the Ao to the left of the spine, whereas in situs inversus, they are reversed. In dextro-isomerism (asplenia syndrome), the Ao and IVC are together on either side of the spine with the Ao anterior to the IVC. In levo-isomerism (polysplenia syndrome), the Ao is in the midline and the azygos is posterior to the aorta either on the right or on the left of the spine, depending upon whether there is azygos or hemiazygos continuation of the infrahepatic interruption of the IVC. Thus, the relative positions of the Ao and IVC are useful in the assessment of the atrial situs.

Figure 10 Chest X-ray of a neonate with isolated levocardia; i.e., levocardia with situs inversus with the stomach (Sto) on the right and the liver (Liv) on the left. Markedly dilated Sto is likely related to intestinal obstruction secondary to malrotation. No displacement of trachea (Tr) is seen

Figure 11 Utility of P wave axis (vector) in the frontal plane: P wave axis between 0° and $+90^\circ$ suggests situs solitus of the atria (normal), P wave axis between $+90^\circ$ and $\pm 180^\circ$ is indicative of situs inversus and P wave axis between 0° and -90° is likely to be coronary sinus rhythm; the last is not usually helpful in situs localization

Figure 12 ECG demonstrating normal P wave vector of $+45^\circ$ with positive P waves (long arrows) in both leads I and aVF; this indicative of situs solitus. Also note Q waves in leads V5 and V6 (small arrows) and no Q waves in right chest leads; this is suggestive normal septal depolarization and, therefore, normal interventricular relationship

Figure 13 ECG demonstrating P wave vector of $+135^\circ$ with negative P waves in lead I and positive P wave aVF (thick arrows); this indicative of situs inversus. There are no Q waves in chest leads; this pattern is not helpful in ventricular localization

Venoatrial concordance During the embryonic period, the IVC is connected to the sinus venosus, which later becomes right atrium. Consequently, the IVC is on the side of the right atrium. Therefore, right-sided IVC is associated with situs solitus and left-sided IVC with situs inversus. The position of the IVC is easily seen by echocardiography and helps localize the right atrium. More invasive

methods such as nuclear angiography or catheter position during cardiac catheterization are also reliable indicators. However, in the presence of infrahepatic interruption of the IVC with either azygos or hemiazygos continuation, situs determination cannot be made because of absence of IVC.

Transesophageal echocardiography/Selective atrial angiography/Surgical inspection The right atrial appendage is broad, large and pyramidal whereas the left atrial appendage is narrow, small and tubular. If transesophageal echocardiography, selective atrial angiography or surgical inspection is performed for other reasons, the distinctive atrial appendage shapes are useful to assess atrial situs.

2. Ventricular Relationship

There may be either one (single) ventricle or two ventricles; such a differentiation can be made by noninvasive studies such as echocardiography (**Fig. 21**) or by angiography. If there are two ventricles, one needs to determine, if there is normal right-to-left relationship or the ventricles are inverted. This may be ascertained by the following methods:

Electrocardiogram Electrocardiogram patterns of QRS morphology with qRs to indicate left ventricle (LV) and Rs to indicate right ventricle (RV) are not reliable because right ventricular hypertrophy is seen in most patients with cardiac malposition. In addition, single ventricle is present in many of these patients. However, the initial QRS vector may be useful. In patients with normally related ventricles (the RV on the right and the LV on the left), initial septal depolarization produces Q waves in leads V5 and V6 without a Q wave in leads V1 and V2 (**Fig. 12**). In patients with inverted ventricles [the morphologic left ventricle (MLV) is on the right and the morphologic right ventricle (MRV) on the left], the AV conduction system is also inverted; this will result in Q waves in leads V1 and V2 and no Q waves in leads V5 and V6 (**Fig. 14**). Whereas initial QRS vector analysis had good theoretical basis, because of severe right ventricular hypertrophy (or single ventricle) and varying degrees of rotation of the heart that is seen in many of the cardiac malposition patients may make such analysis not completely accurate.

Echocardiography and angiocardiology The characteristic anatomic features of the ventricles, namely, architecture of the ventricles, AV to semilunar valve relationship and AV valve attachments are useful in identifying relative positions of the ventricles. The MRV is coarsely trabeculated with triangular shape whereas the MLV is smooth-walled with fine trabeculations and is foot-shaped. It should also be noted that AV valves go with the ventricles; the mitral valve is always an essential component of the LV while the tricuspid is an integral part of the RV. Also, the mitral and aortic valves are in fibrous continuity with each other suggesting MLV since the LV does not have conal muscle while crista supraventricularis separates the tricuspid and pulmonary valves from each other in the RV. Furthermore, the medial leaflet of the mitral valve is attached to the interventricular septum somewhat higher than the attachment of the tricuspid valve (**Fig. 22**). Another key principle is the loop rule; as per the loop rule, semilunar valve relationship are predictive of the ventricular looping which in turn localizes the ventricles: aortic valve to the right of the pulmonary valve indicates d-loop, i.e., the RV is on the right side and aortic valve to the left of the pulmonary valve suggests l-loop, i.e., RV is on the left. Coronary artery anatomy is also useful in that the left anterior descending coronary artery arises from the left coronary artery in d-loop while the left anterior descending coronary artery arises from the right coronary artery in l-loop. All the above portrayed features can be defined by deductive echocardiography and selective cine angiography.

Figure 14 ECG demonstrating P wave vector of -45° with positive P waves in lead I and negative P wave AVF (long arrows); this is indicative of coronary sinus rhythm. Such a rhythm is unlikely to be helpful in situs localization. However, coronary sinus rhythm may be associated with persistent left superior vena cava and infrahepatic interruption of the inferior vena cava. Note Q waves in right chest leads (small arrows) and no Q waves in left chest leads; this is likely to indicate ventricular inversion. However, such pattern may be seen with severe right ventricular hypertrophy

Figures 15A and B Chest X-rays of two infants with dextrocardia with nearly equal sized hepatic lobes (and midline liver). The trachea (Tr) is in the middle. These infants were later shown to have asplenia syndrome. The positions of the umbilical venous catheters (UVC) and umbilical arterial catheters (UAC) are shown

Figures 16A and B Diagrammatic portrayal of bronchial anatomy. (A) *Situs solitus*: The right bronchus is short and wide and descends rather steeply while the left bronchus is long and narrow and descends more horizontally and (B) *Situs inversus*: The tracheobronchial tree pattern is reversed with the morphologic right bronchus on the left and the morphologic left bronchus on the right

Figures 19A and B Diagrammatic portrayal of bronchial anatomy in dextroisomerism and levoisomerism. (A) Asplenia syndrome. Both bronchi appear as morphologic right bronchi and (B) Polysplenia syndrome. Both bronchi appear as morphologic left bronchi

Figure 17 Chest X-ray of a baby with situs solitus; the morphologic right bronchus (MRB) is short and wide and descends rather steeply while the morphologic left bronchus (MLB) is long and narrow and descends more horizontally. The positions of the umbilical venous catheters (UVC) and umbilical arterial catheters (UAC) are marked

Figure 18 Chest X-ray of a child with dextrocardia with the morphologic right bronchus (MRB) on the left and the morphologic left bronchus (MLB) is on the right indicating situs inversus. The viscera are also inverted with the liver (Liv) on the left and the stomach (Sto) on the right

3. What is the Status of Atrioventricular Connections?

The connections between atria and ventricles may be concordant (right atrium connected to the RV and the left atrium to the LV), discordant (right atrium connected to the LV and the left atrium to the RV), only one common AV valve is present or one of AV valves may be atretic. Lastly overriding or straddling of the AV valve may be present or criss-cross relationship may be present. Again, these features may easily be identified by detailed echocardiograms, and if necessary by angiography may be performed.

4. How are the Great Arteries Related to Each Other and with Ventricles?

The great artery relationship may be normal in which case the aorta (aortic valve) is inferior, posterior and to the right of the pulmonary artery (pulmonary valve), may be inverted in which the aorta is to the left of the pulmonary artery, may have d-transposition with the aorta superior, anterior and to the right of the pulmonary artery, or may have l-transposition with the aorta superior, anterior and to the left of the pulmonary artery. The relationship may be portrayed as malposed, if it is abnormal, but cannot easily be placed into any of the above groups.

The connection of the great arteries with ventricles is also variable in that it may be concordant with the aorta arising from the LV and the pulmonary artery from the RV (normal), discordant with the pulmonary artery coming off of the LV and the aorta from the RV (d-TGA with d-loop or l-TGA with l-loop), double-outlet right ventricle (DORV) or double-outlet left ventricle with both great arteries arising from the RV or LV, respectively. There may be one vessel coming off the ventricles, truncus arteriosus or, there may be atresia of one of the semilunar valves or great vessels, i.e., pulmonary atresia or aortic atresia. Most of these relationships may be defined by echocardiography, although angiography or other imaging studies [CT scan or magnetic resonance imaging (MRI)] may be needed for confirmation.

5. What is the Conotruncal Relationship?

The conal tissue may be located in subpulmonary or subaortic regions, present bilaterally or absent. Subpulmonary conus is seen in normal hearts and subaortic conus is present in transposition. Bilateral conus is likely in DORV and conus is absent double-outlet left ventricle. The anteroposterior and superior-inferior relationship of semilunar valves indicates conal anatomy; the more conus beneath a semilunar valve, the higher and anterior is that valve.

Summary of Segmental Analysis

While cardiac position and atrial situs can be successfully appraised by routine physical examination, chest X-ray and

Figures 20A to C Selected video frame from a short axis echocardiographic view of a normal neonate demonstrating the inferior vena cava (IVC) on the right of the spine (Spi) and the aorta (Ao) on the left (A). The IVC is usually larger than aorta. Doppler flow patterns confirm higher velocity arterial flow pattern in the DAo (B) and low velocity venous flow in the IVC (C). This pattern suggests situs solitus

Figures 21A and B (A) Selected video frame from apical four-chamber echocardiographic view of a child with two ventricles. The right (RV) and left (LV) ventricles (thick arrows) are marked. The ventricular septum (VS) is shown (thin arrow) and (B) Selected video frame from apical four-chamber echocardiographic view a child with single ventricle (SV). No VS is seen
Abbreviations: LA, left atrium; RA, right atrium.

ECG, ventricular relationship, AV connections, great artery and conotruncal relationship need echocardiogram, angiocardiogram or other imaging studies for precise evaluation.

Segmental Assignment

After each cardiac segment is assessed, they may be suitably designated; atrial situs: S, solitus; I, inverted; A, ambiguous; ventricular situs: D, RV to the right or L; RV to the left; semilunar valves: S, solitus; I, inverted; D, d-transposition; L, l-transposition. For instance, normal hearts may be designated as (S,D,S), complete transposition as (S,D,D), corrected transposition as (S,L,L) and so on.

Associated Defects

After the sites of atria, ventricles and great arteries are established, the associated defects such as atrial and ventricular septal defects (VSDs), valvar stenosis or atresia and other abnormalities may be identified by usual methods such as physical examination, ECG, and echocardiography or angiocardiography or other imaging studies.

HETEROTAXY SYNDROMES

During embryonic development, left to right asymmetry is set-up in normal individuals with right-sided liver, left-sided stomach, tri-lobed right lung, bi-lobed left lung and normal right to left relationship of the atrial chambers and other structures. If embryological failure of development of such asymmetry occurs for any reason, heterotaxy syndromes such as asplenia, polysplenia and similar syndromes occur.

While papers on heterotaxy syndrome were published in 1826 by Martin and by Breschet, these entities are not commonly known until the publication of reports of case series by Ivemark and Putschar and Manion in mid-1900s. The prevalence of these syndromes is very low at 1 in 10,000 to 1 in 20,000 livebirths. Pathologic, clinical and diagnostic features and management of asplenia and polysplenia syndromes will be reviewed hereunder.

Extracardiac Anomalies

Asplenia syndrome The spleen is obviously absent in asplenia syndrome. As a result, the culling and pitting functions of the spleen are missing and consequently, Howell-Jolly and Heinz bodies as

Figures 22A and B (A) Selected video frame from apical four-chambered echocardiographic view of an infant with normal ventricular relationship; note higher level of attachment of the mitral valve (MVA) compared to the tricuspid valve attachment (TVA); and (B) Selected video frame from apical four-chamber echocardiographic views of an infant with ventricular inversion; note higher level of attachment of the mitral valve (MVA) on the right compared to the tricuspid valve attachment (TVA) on the left, indicating that the ventricles are inverted. This is a reversal of what is shown in A

Abbreviations: LA, left atrium; MLV, morphologic left ventricle; MRV, morphologic right ventricle; RA, right atrium.

well as abnormally shaped red cells (which are ordinarily removed by normally functioning spleen) are seen in the blood smear. Situs abnormality, generally described as situs ambiguous is seen in that there is bilateral right-sidedness (dextro-isomerism). The lungs are tri-lobed with eparterial bronchi on both sides. The hepatic lobes are symmetrical with the left lobe larger than the right and the liver is in the midline. The location of stomach variable; it may be on the left or right side. Malrotation of the midgut is seen with resultant intestinal obstruction and sometimes it may be the presenting symptom. The gallbladder is in the midline or may be absent.

Polysplenia syndrome In polysplenia syndrome, as the name implies, there are 2–9 equal-sized splenic masses, each of which is smaller in size than normal spleen, but total splenic tissue is comparable to normal splenic mass. However, functional asplenia is seen in some of the patients and Howell-Jolly and Heinz bodies may also be present in the blood smear. The situs is ambiguous in polysplenia syndrome, but with bilateral left-sidedness (levoisomerism). In general, there is a propensity for preservation of left-sided structures with hypoplasia or absence of right-sided structures. The lungs are bi-lobed with hyparterial bronchi on both sides. The liver is midline with somewhat symmetrical hepatic lobes. The stomach is situated either on the left or right side of the abdomen, malrotation of midgut may also be present which may either be nonrotation and less commonly reversed rotation. These abnormalities can result in intestinal obstruction, similar to that described in asplenia syndrome. The gallbladder is usually absent and biliary atresia may be seen.

Cardiac Defect

Asplenia syndrome Dextrocardia is frequent in asplenia syndrome patients. The incidence of cardiac abnormalities is very high although one earlier study cites only 63% prevalence of CHD. Both atrial chambers are morphologically right atria and common atrium is frequent. Atrial septal defects (ASDs) are typically seen with ostium primum type being more frequent; this may be a part of common AV canal. Common AV canal is present in the majority

patients. Single ventricle and ventricular inversion are common. Most patients with two ventricles have VSDs. Great arteries exhibit malposition which may manifest either as complete transposition (d-TGA), corrected transposition (l-TGA) or DORV. Atresia of the pulmonary valve or severe stenosis is present in almost all patients. Anomalies of the systemic veins, such as bilateral superior venae cavae are frequent in asplenia syndrome. Total anomalous pulmonary venous connection (TAPVC) is seen in two-thirds of the patients. However, partial anomalous pulmonary venous connection is uncommon.

Polysplenia syndrome Dextrocardia and levocardia are nearly equally present in polysplenia syndrome. Because of levoisomerism both atria are morphologically left atria. Common atrium is rare; this is in contradistinction to that seen in asplenia syndrome. ASD is present in 90% of patients; it is of ostium primum type in half of these subjects and ostium secundum in the remaining half. More often than not both ventricles are present and ventricular inversion is unusual. VSD is seen in 75% of patients while common AV canal is present only in 25% of patients. Complete transposition is unusual and DORV is uncommon. Pulmonary valvar atresia or severe stenosis is present only rarely; most patients do not have pulmonary outflow tract obstruction. Infrahepatic interruption of the IVC with azygos or hemiazygos continuation and bilateral superior vena cavae are commonly seen in polysplenia syndrome. Partial anomalous pulmonary venous connection is present in 50% of patients and TAPVC in one-third of patients; the pulmonary veins are connected directly to the venous atrium. Hypoplastic left heart syndrome and subaortic obstruction are rarely seen in polysplenia.

Clinical Features

Asplenia children present with severe cyanosis because of pulmonary oligemia secondary to complex CHD with severe PS or pulmonary atresia that they characteristically have. Signs of CHF are remarkably absent. Polysplenia babies, on the other hand, have mild or no cyanosis, often have increased pulmonary blood flow and may have signs of CHF.

When to Suspect Asplenia/Polysplenia Syndromes

The heterotaxy syndromes may be suspected, if there is inconsistency of situs by various methods discussed in the preceding section. Other features that increase the possibility are: (1) symmetric bronchial pattern (**Fig. 19**) with either dextro-isomerism (bilateral morphologic right bronchi) or levoisomerism (bilateral morphologic left bronchi); (2) divergence between cardiac position and viscerotaxial situs (isolated dextrocardia or isolated levocardia); (3) midline or symmetric liver on chest X-ray; (4) abnormal venous shadows on chest X-ray to indicate infrahepatic interruption of the IVC (or demonstrated by echo or angiographic studies) and (5) malrotation of the gut (nonrotation or reversed rotation).

Confirmatory Studies Useful in Splenic Syndromes

Howell-Jolly bodies and Heinz bodies As pointed out earlier, the culling and pitting functions are absent in asplenia and as a result, Howell-Jolly and Heinz bodies as well as abnormally shaped red cells which are normally removed by functioning spleen are seen in the peripheral blood smear. Indeed, some authorities have been suggested that in their presence a presumptive diagnosis of asplenia syndrome should be made. However, polysplenia patients may have functional asplenia resulting in appearance of Howell-Jolly and Heinz bodies in the blood smear. In addition, functional asplenia may be seen in babies with severe cyanotic CHD. Accordingly, the Howell-Jolly and Heinz bodies in the peripheral blood smear are not as useful in the diagnosis of asplenia in the neonate as once believed.

Barium gastrointestinal series When heterotaxy syndromes are suspected barium gastrointestinal studies should be undertaken in order to detect malrotation of the midgut. Malrotation of the gut in association with infrahepatic interruption of IVC is highly suggestive of polysplenia syndrome.

Abdominal ultrasound Abdominal ultrasound studies may be able to identify the liver and spleen and distinguish normal from asplenia and polysplenia. While this is possible in the hands of experienced ultrasonographers, rather similar ultrasound appearance of both liver and spleen makes this distinction confusing.

Radioisotopic scanning of the liver and spleen Radioisotopic scanning of the liver and spleen with ^{99m}Tc Technisium sulfur colloid is widely used to detect abnormalities of the liver and spleen. However, since such scanning tests the function of reticuloendothelial cells, which are present in both liver and spleen, it may be difficult to easily identify and separate these structures, particularly when they are abnormal. In addition, hypofunction of the splenic tissue in polysplenia syndrome may further confuse this issue. Use of radioactive material that specifically images liver or spleen (for example ^{99m}Tc Pipida) and superimposing them on ^{99m}Tc Technisium sulfur colloid scan may help to identify the splenic abnormalities.

Selective angiography Selective celiac-mesenteric artery and abdominal aortography may help to identify multiple rounded vascular densities of the splenic tissue.

DIAGNOSIS

Whenever cardiac malpositions and/or heterotaxy syndromes are suspected, segmental analysis, discussed earlier should be pursued and atrial, ventricular and great artery locations identified and segmental subsets assigned. Once the sites of atria, ventricles and great arteries are known, the associated defects such as ASDs, VSDs, valvar and vascular stenosis or atresia, etc. may be identified by cautious review of the history, systematic physical examination

and detailed analysis of ECG, chest X-ray and echocardiographic studies. If necessary, other noninvasive studies such as MRI and computed tomographic studies and invasive cardiac catheterization and selective cineangiography may be performed to authenticate the diagnoses.

MANAGEMENT

Palliation

Initial management of these babies is similar that used in other cyanotic CHD. The infant's temperature is monitored and neutral thermal environment maintained. If there is hypoxemia, oxygen is administered. In cyanotic CHD neonates, O_2 concentration should not be more than 40% because of fixed intracardiac right-to-left shunting higher levels of ambient O_2 do not increase O_2 saturation. Instead, the lungs are exposed to damaging levels of O_2 . When present, metabolic acidosis ($\text{pH} < 7.25$), is treated with sodium bicarbonate (usually 1–2 mEq/kg diluted half and half with 5% or 10% dextrose solution). If respiratory acidosis is present, suctioning, intubation and assisted ventilation is provided, as deemed appropriate. Because hypoglycemia may be a significant problem, the babies' serum glucose is watched. If hypoglycemia ($< 30 \text{ mg}/100 \text{ mL}$) is present, 15–20% dextrose solution is administered intravenously. Similarly, calcium concentration is monitored, and if hypocalcemia is found, it should be corrected.

After the baby is stabilized, treatment should address the physiologic abnormality produced by multiple defects that many of these heterotaxy babies are likely to have. In patients with pulmonary oligemia secondary to pulmonary atresia or severe pulmonary stenosis and large interventricular communication (or single ventricle), administration of PGE_1 (initial dose of 0.05–0.1 mcg/kg/min, slowly decreasing to 0.02 mcg/kg/min) is the first step. This is followed by modified Blalock-Taussig shunt. Neonates with markedly increased pulmonary flow and CHF should be treated with anti-congestive measures. Subsequently, surgical repair of the defect is performed (if the defect is amenable to total correction). If that is not possible, pulmonary artery banding may be performed first to decrease the pulmonary artery pressure and flow and to prevent pulmonary vascular obstructive disease. A plan for total correction later should be made. However, it should be understood that because of high pulmonary vascular resistance at birth and slow regression of the resistance in the presence of large interventricular communication, these babies usually do not go into CHF within the first few days to weeks of life. These babies may be carefully observed with intervention planned a few weeks later. Babies with obstructive type of TAPVC should undergo immediate surgical correction.

Additional Surgery

After initial palliation, methodical review of all the studies should be made to determine the feasibility of biventricular repair. If such is not possible, consideration for single ventricle palliation should be given with palliation early as detailed in the preceding section, bidirectional Glenn at about 6 months of life and Fontan conversion a year or 2 years later.

Noncardiac Issues

Because of lack of splenic function, these babies are at a higher risk for development of infection. During infancy, they should receive prophylactic doses of amoxicillin and switched later in childhood to penicillin. The risk of development of gastrointestinal obstruction is high. Consequently, prophylactic Ladd's procedure is performed routinely at many institutions to prevent gastrointestinal obstruction.

IN A NUTSHELL

1. Cardiac malpositions and heterotaxy syndromes have high prevalence of CHD; the prevalence is significantly higher than normal babies.
2. The incidence varies with the associated viscerotrial situs; isolated levocardia and isolated dextrocardia have the highest frequency.
3. The best approach to diagnosis is segmental analysis. In segmental analysis, the viscerotrial situs, ventricular location, status of atrioventricular connections, relationship of the great arteries and conotruncal relationship are determined with the help of ECG, chest X-ray and echocardiographic studies and when necessary other imaging studies, including angiography.
4. After the sites of atria, ventricles and great arteries are identified, the associated defects such as ASD, VSD, valvar and vascular stenosis or atresia may be determined by review of the history, physical examination and analysis of chest X-ray, ECG and echocardiographic studies.
5. At presentation, addressing the physiologic abnormality produced by the defect complex, whether it be augmenting pulmonary blood flow or restricting it, is the initial step. Other associated defects should also be addressed accordingly. Biventricular or univentricular repair depending upon the patients' anatomy should be planned.

Chapter 40.12

Ventricular Septal Defects

IB Vijayalakshmi

Ventricular septal defect (VSD) is a developmental defect of the interventricular septum (IVS) wherein a communication exists between the two ventricular cavities. It can occur in isolation or as a part of more complex defects. Isolated VSDs can be repaired surgically with very low mortality rate. Recently, nonsurgical transcatheter device closure of VSDs is in vogue.

EPIDEMIOLOGY

Isolated VSDs are the second most common congenital heart disease (CHD) encountered after bicuspid aortic valves and occur in approximately 2 out of every 1,000 livebirths and constitute over 20–30% of all CHDs. The doubly committed subarterial or juxta-arterial defects are more common (30%) in Asian populations, whereas muscular and multiple defects are less common.

ETIOPATHOGENESIS

The etiology is multifactorial. Interaction between hereditary predisposition and environmental influences results in the defect. In the majority of patients with an isolated VSD (95%), the defect is not associated with a chromosomal abnormality and the cause is unknown. Studies have shown an interaction between *TBX5*, *GATA4*, and *NKX2.5*, suggesting that transcriptional activation may be responsible for septal defects. The VSDs may be associated with exposure to certain environmental factors during pregnancy especially within the first 8 weeks of gestation. Some of the environmental factors are maternal phenylketonuria, diabetes mellitus or exposure to febrile illness, especially rubella, influenza, or teratogens such as alcohol, cocaine, marijuana, ibuprofen, anticonvulsants (hydantoin, carbamazepine) or organic solvents.

Siblings of patients with VSD have three times the incidence of VSD as compared to general population. VSDs are found in 3.3% of the first-degree relatives and in nearly 3–10% of siblings of the index case. Maternal VSDs have a recurrence risk of 9–10%, whereas with paternal VSDs, the recurrence risk in the offspring is just 2–3%.

EMBRYOLOGY

The normal development of the IVS is a complex process and depends upon the endocardial cushions, conotruncal ridges, growth of tissues at the crest of IVS and the muscular septum. The

VSDs result from a deficiency of growth or a failure of alignment or fusion of the component parts of the IVS beyond the first 7 weeks of intrauterine life. The reason for this delayed or incomplete closure is still unknown.

CLASSIFICATION

The VSDs are classified depending on their locations on the IVS by Soto as seen from right ventricle (RV). They are divided into four types: (1) Perimembranous, (2) Muscular, (3) Outlet and (4) Inlet defects (**Table 1**). The diagrammatic representation of various locations of VSDs is given in **Figure 1**. The hemodynamic classification of VSDs is given in **Table 2**.

CLINICAL FEATURES

The signs and symptoms begin to develop when the fetal pulmonary hypertension starts declining sufficiently to permit left-to-right shunting. The clinical manifestation of isolated VSDs has a wide spectrum which varies depending upon the size of the defect and the magnitude of the shunt. It may range from being asymptomatic to severe heart failure. The infants with large VSDs present with symptoms due to congestive heart failure (CHF) in early infancy (2–6 weeks to 2–3 months). The signs and symptoms of VSDs are given in **Table 3**.

The systolic murmurs in outlet defects are heard in left second intercostal space (ICS) and may radiate upwards to the left into the suprasternal notch and into left side of neck. When the shunt is large ($Q_p/Q_s > 2:1$) a short mid-diastolic murmur is heard at the apex due to the increased flow across the mitral valve. When a small VSD is associated with severe aortic regurgitation (AR), one can hear a *to* and *fro* murmur. The *to* murmur is harsh long systolic crescendo and *fro* murmur is soft blowing early diastolic decrescendo murmur in the left second and third ICS. The patient will have the peripheral signs of AR. The jugular venous pulse is not raised in VSD.

NATURAL HISTORY

The natural history of a VSD varies widely, ranging from spontaneous closure to CHF to death in early infancy. It depends on type of the defect, its size, number and other associated anomalies. Spontaneous closure occurs in 25–40% of small VSDs by age of 2 years; 90% of VSDs that close do so by age of 10 years. The spontaneous closures are due to: (1) ingrowth of fibrous tissue with endocardial proliferation with septal aneurysm (may cause thromboembolism); (2) adherence of septal tricuspid leaflet resulting in tricuspid regurgitation; (3) prolapse of aortic cusp through the defect leading to AR and (4) vegetation of infective endocarditis which may lead to death.

Table 1 Types of ventricular septal defects with synonyms and anatomical features

Type of VSD	Synonyms	Anatomy	Conduction bundle
Perimembranous defects (80%)	Infracristal, subaortic, membranous, conoventricular	Membranous septum with extension into the adjacent inlet, outlet or muscular septum. They lie in the outflow tract of the LV immediately beneath the aortic valve	Posteroinferior margin of the defect
Muscular (5–20%)	Trabecular	Bounded by the muscular septum often multiple, it is often referred to as <i>Swiss-cheese</i> type of VSDs	Remote
Outlet (5–7%)	Supracristal, conal, infundibular, subpulmonary, doubly committed subarterial, doubly committed juxta-arterial	Subpulmonic communicating with the RV outflow tract above the supraventricular crest	Remote
Inlet (8%)	Canal-type, endocardial cushion-type, AV septum-type, inlet, juxtatriscuspid	Posteriorly and inferiorly to the membranous septum	Remote or the conduction system borders the defect superiorly

Abbreviations: VSD, ventricular septal defect; AV, atrioventricle; LV, left ventricle.

Figure 1 The anatomic position of various types of ventricular septal defects

Small defects may be closed by prolapse of aortic cusp leading to AR. The AR is due to Venturi's effect, seen more in subpulmonic VSDs (30%) than perimembranous VSDs (5–8%). It is more between the age of 5 years and 9 years. In nearly 5–10% of moderately to large VSDs, infundibular pulmonary stenosis (Gasul's effect) may develop. Large defects often develop left ventricular (LV) failure, pulmonary hypertension (Eisenmenger syndrome) and RV failure. Therefore, clinicians must not rush to tell parents that VSD in their child will close spontaneously. It must be told that every case must be followed up and evaluated clinically and by echocardiography (echo) to see whether the defect is becoming smaller.

DIAGNOSIS

Electrocardiogram (ECG) Inlet VSDs have left axis deviation (LAD). In multiple VSDs, 40% can have LAD. There can be broad notched left atrial P waves in L1 and L2 with broad P terminal force in V1. The tall R waves may be associated with tall, peaked T waves in L2, L3 and aVF. The leads V5-6 show prominent Q waves, tall R waves and tall, peaked T waves.

Transthoracic echocardiography (TTE) The TTE with color Doppler is widely used to diagnose VSD. The color Doppler can detect as small as 2 mm VSDs. The objectives of TTE assessment of a VSD are to define its site, size, hemodynamic effects, complications and associated lesions. This is accomplished by viewing the defect from multiple imaging planes (**Figs 2A to C**). The physiologic consequences can be assessed by the degree of LV

and left atrial dilatation as well as RV hypertrophy. The trans-VSD gradient of greater than 64 mm of Hg indicates a restrictive VSD with a normal pulmonary artery pressure. Also one needs to assess for potential complications such as bacterial endocarditis (**Figs 3A and B**) aortic cusp prolapse or AR (**Figs 4A and B**).

MANAGEMENT

The management of VSDs depends on the size, site, number of defects and magnitude of the shunt and also depends on the associated lesions and the complications. The small VSDs are usually asymptomatic and have an excellent long-term prognosis. They require just subacute bacterial endocarditis (SBE) prophylaxis. The small VSDs need periodic follow-up once in 6 months with monitoring of the symptoms, weight gain, and appearance of any new murmur of AR. Surgical closure of small VSDs is indicated (a) when there is associated moderate or severe AR and (b) if there has been a previous episode of endocarditis. The therapies available for management of VSDs are: (1) Medical, (2) Transcatheter, (3) Surgical and (4) Hybrid surgery.

Management of VSD in Newborn

Unless the defect is very small and uncomplicated, newborns with VSD need careful clinical and detailed echo reevaluations initially weekly and then bimonthly for first 8 weeks to detect early signs of volume overload. Detailed echo assessment has replaced catheterization. Prompt treatment of the lower respiratory infection (LRTI) and correction of anemia, must not be delayed. If the pulmonary artery systolic pressure is greater than half the systemic systolic pressure and CHF is difficult to manage medically with oral diuretics, then defect needs surgical closure without delay in the newborn period.

Management of VSD in Infants

If congestive failure is not severe, medical management is continued with oral diuretics only for a trial period of first 6 months. If the child is not gaining weight, is getting repeated LRTI and pulmonary artery systolic pressure is greater than half of the systemic systolic pressure, then the infant's defect is closed without further waiting. On the other hand, if the pulmonary artery pressure falls to less than half the systemic pressure, the infant is then managed medically till the end of their 2nd year of life. This decision must be supported by clinical improvement, weight gain, echo evidence of reduction in size and an increase in trans-VSD gradient.

Few children will remain symptomatic and continue to have cardiac enlargement beyond the 2nd year of life due to large left-to-right shunt despite the normal pulmonary arterial pressure. In such children surgical or device closure is recommended before the child enters the school. The criteria are: (i) QP:QS > 1.8:1, (ii) QP:QS > 1.5:1 in older children without severe pulmonary

Table 2 Hemodynamic classification of ventricular septal defects

	Small	Moderate	Large
Size (compared to aortic root)	< 1/3	1/3–2/3	> 2/3
Size orifical area (cm ² /m ²)	< 0.5	0.5–1.0	≥ 1.0
Peak systolic pressure gradient between LV and RV (mm Hg)	>64 High	≥ 20	< 20
Pulmonary/aortic systolic pressure ratio	<0.3	< 0.66	> 0.66
Shunt—Qp/Qs	< 1.5:1	> 1.5–2.2:1	> 2.2:1
LA/LV volume overload	Nil/minimal	+	++
PA pressure/PVR	Normal	↑	↑↑

Abbreviations: LV, left ventricle; RV, right ventricle; LA, left atrium; PA, pulmonary artery; PVR, pulmonary vascular resistance.

Table 3 Clinical features depending on size of ventricular septal defects

Size of VSD	Symptoms	Signs	Chest X-ray	ECG
<i>Small</i>	Asymptomatic, may be detected by murmur on a routine check-up	Precordial systolic thrill best felt in the left third and fourth ICS at the left LSB, grade 4/6, harsh holosystolic, crescendo-decrescendo murmur, best heard along the left LSB. In very small apical or muscular defects the murmur is soft, grade 2/6 or less, as the defect practically closes during systole	Normal	Normal
<i>Moderate</i>	Prominent pulsations over the precordium, mild tachypnea, fatigue or cough during feeding, lack of adequate growth with one or more episodes of LRTI. Effort intolerance and fatigue in older children	Precordial pulsations are visible due to the volume overload of LV. The apical impulse is LV type, hyperdynamic and is down and out indicating cardiomegaly. P2 is normal or mildly increased in intensity. Grade 3/6, low-pitched, systolic decrescendo murmur in LSB with mid-diastolic murmur in the mitral area	Moderate cardiomegaly, prominent PVM in both central and peripheral portions of the lung fields. The main PA segment is prominent. LA enlargement with wide carinal angle	Sinus rhythm, PR interval is normal or slightly prolonged. Normal QRS axis
<i>Large</i>	Infants present with symptoms due to CHF in early infancy (2–6 weeks to 2–3 months) tachypnea, lower chest retractions, feeding difficulties with suck rest suck cycle, excessive sweating of forehead, repeated LRTI and failure to thrive	Malnourished, tachypnea, chest retractions, precordial bulge with bilateral Harrison sulcus, prominent precordial pulsations, apical impulse is LV type, hyperdynamic and is down and out indicating cardiomegaly. P2 is palpable and loud with a narrow split. LV S3 can be present. Long crescendo decrescendo murmur in LSB	Cardiomegaly, pulmonary plethora, prominent main PA with RV enlargement. LV apex is displaced posteriorly due to RVH	Right axis deviation, biventricular hypertrophy is seen in the mid-precordial leads as large equidiphasic RS complex (> 50 mm), called as <i>Katz-Wachtel phenomenon</i> . With tall R wave in lead V1, deep Q waves, tall R and peaked, tall T waves V5–6
<i>Large VSD with high PVR</i>	Do not have much symptoms at rest, but have exertional dyspnea, cyanosis	Cyanosis and clubbing may be present. Left para sternal heave present. RV S3 present with RV type apical impulse. Very short soft decrescendo murmur or rarely no murmur is heard in balanced shunts. The ejection click may be heard due to PAH. P2 is quite loud, palpable with narrow split. No diastolic rumble at apex but a short early diastolic murmur of pulmonary regurgitation (Graham Steel's murmur) may be heard in left upper parasternal area	No cardiomegaly, RVH, aneurysmally dilated main PA, LPA and RPA, decreased PVM in the outer third of the lung fields (peripheral pruning)	Right axis deviation, P pulmonale, RVH
<i>Eisenmenger complex</i>	Easy fatigability chest pain, syncope and hemoptysis	Cyanosis, clubbing, loud palpable P2, parasternal heave, short soft systolic murmur in PA	Water jug appearance	Peaked P waves, right axis, tall monophasic R with small q and small s wave in V1

Abbreviations: CHF, congestive heart failure; CXR, chest X-ray; ECG, electrocardiogram; ICS, intercostal space; LRTI, lower respiratory tract infection; LA, left atrium; LPA, left pulmonary artery; LSB, left lower sternal border; LV, left ventricle; PA, pulmonary artery; PVM, pulmonary vascular markings; RPA, right pulmonary artery; RV, right ventricle; RVH, right ventricular hypertrophy.

vascular resistance (PVR) and (iii) All patients older than 2 years, if pulmonary artery systolic pressure is greater than half the systemic arterial systolic pressure or mean pulmonary artery pressure is greater than 20 mm of Hg or PVR/systemic vascular resistance (SVR) ratio exceeds 0.2:1. The surgery is recommended, if calculated PVR is less than 11 units/m² or PVR/SVR ratio is less than 0.7:1 provided the QP:QS is still greater than 1.5:1. The patients with moderate VSDs need periodic medical follow-up. They need nutritional support for failure to thrive (FTT) and treatment of recurrent respiratory infections.

The indications (**Table 4**) and parameters for operability are presence of:

- Severe pulmonary arterial hypertension (PAH) in children less than 2 years
- Clinical symptoms of CHF, cardiomegaly, S3 and a mid-diastolic flow rumble at the apex

- Cardiomegaly with pulmonary plethora in Chest X-ray
- Presence of left ventricular hypertrophy (LVH) with volume overload in ECG
- Dilatation of left atrium (LA) and LV with sub-systemic PA pressure in echo
- Pulmonary vascular resistance index less than 6 Wood units and/or a ratio of pulmonary to SVR (Rp:Rs) less than 0.35 as catheterization data.

The closure of VSDs is based on the type of the VSD and ease of access. The current trend is to try to avoid a ventriculotomy as far as possible. Surgical closure is done in all large defects, inlet and outlet VSDs and in small VSD with past history of SBE. Neither the age nor weight is prohibitive in resorting to surgery. The nutritional support is vital and aimed to increase the caloric density of feeds. The LRTI has to be treated with antibiotics. The CHF is treated with a combination of drugs (**Table 5**).

Figures 2A to C (A) Inverted image of apical four-chamber view shows a large subaortic VSD; (B) Inverted image of apical four-chamber view with color Doppler shows mid-muscular ventricular septal defect (VSD) (arrow) with left-to-right shunt; and (C) Apical four-chamber view shows multiple Swiss cheese VSDs

Figures 3A and B Parasternal long-axis view with color Doppler shows small perimembranous ventricular septal defect (VSD) with septal aneurysm (arrow) and (B) Parasternal long-axis view with color Doppler shows large vegetation on right ventricle (RV) side closing the VSD

Figures 4A and B (A) Parasternal short-axis view with color Doppler shows subaortic ventricular septal defect (VSD) (in 9–10 o'clock position) with a vegetation and (B) Parasternal short-axis view with color Doppler shows subpulmonic VSD (1–2 o'clock position) just beneath the pulmonary valve with AR

Postoperative Follow-up

Children with preoperative PAH or elevated PVR should be followed up for 1–2 years after surgery. SBE prophylaxis is continued for at least 1 year. Holter monitoring is indicated in: (i) presence of symptoms suggestive of arrhythmia and (ii) in patients with postoperative right bundle branch block (RBBB)/left

anterior hemiblock. A redo surgery or device closure is needed, if residual shunt is significant.

Transcatheter Therapy

All mid-muscular VSDs, apical VSDs and selected cases of moderate sized perimembranous VSDs with at least 4 mm of aortic rim can

undergo nonsurgical transcatheter device closure (**Figs 5A to C**). The major advantages of device closure are absence of scar on the chest, less hospital stay and avoidance of cardiopulmonary bypass (CPB). Amplatzer septal occluder and Amplatzer duct occluder II (ADO II) are used to close VSDs. The ADO II is a very soft device with no polyester material and does not compress the conducting system. As it can be deployed from the aortic end, no arteriovenous looping is required. The arrhythmias are transient; complete heart block has been reported in 2–3% in perimembranous VSD device closure.

Hybrid Surgery

In small infants, when deploying large device is difficult, then hybrid surgery is done. The surgical and nonsurgical device closure is combined to close very large mid-muscular VSDs, especially

in infants with low body weight (< 5 kg). A mini sternotomy is done and then VSD device is deployed via purse-string suture on RV under echocardiographic and fluoroscopic guidance. The advantages are avoidance of CPB, less blood loss and speedy postoperative recovery.

Table 4 The indications for surgery for VSD at different ages

Age	Indications
< 6 months	Uncontrolled congestive heart failure, failure to thrive
6–12 months	Pulmonary hypertension, symptomatic
2–5 years	Qp/Qs > 1.5:1, aortic regurgitation
> 5 years	Aortic regurgitation

Table 5 Drugs and doses for medical management of heart failure in children with moderate-to-large ventricular septal defect (VSD)

Drug	Dosage	Side effects
Diuretics (e.g., furosemide)	<i>Neonates, Premature:</i> Oral: 1–4 mg/kg/dose once or twice daily IM, IV: 1–2 mg/kg/dose administered every 12–24 hours <i>Infants and Children:</i> Oral: 1–6 mg/kg/day divided every 6–12 hours IM, IV: 0.25–2 mg/kg/dose every 6–12 hours	Long-term treatment—hypercalcemia and renal damage and electrolyte disturbances
Angiotensin-converting enzyme (ACE) inhibitors	Captopril—neonates and infants. Initial starting dose is 0.1 mg/kg/dose; gradually increased to 0.5–1 mg/kg/dose TID. Maximum dose is 2 mg/kg/dose Enalapril—older children Initial dose is 0.1 mg/kg/24 hour BID, gradually increasing to 0.5 mg/kg/24 hour BID	BP and renal parameters to be monitored
Digoxin	<i>Controversial:</i> 5–10 mcg/kg/day May be indicated, if diuresis and afterload reduction do not relieve symptoms adequately	

Abbreviations: IM, intramuscular, IV, intravenous.

IN A NUTSHELL

1. The ventricular septal defect is one of the most common CHDs.
2. A good clinical and echocardiographic assessment is important for timely management.
3. Surgery is the age old time-tested method of management for large defects and in inlet, outlet VSDs.
4. Device closure of VSDs, in selected patients, is an attractive alternative to traditional surgery.
5. In this modern era, no patient of VSD should be allowed to develop endocarditis, AR or Eisenmenger syndrome.

Chapter 40.13

Atrial Septal Defects

K Sivakumar

Atrial septal defects (ASD) refer to open communication between right atrium (RA) and left atrium (LA) due to structural congenital defects in most instances. ASDs are classified according to their embryonic origin (**Fig. 1**).

- **Secundum ASD (75%)**—occur in central part of atrial septum in fossa ovalis
- **Primum ASD (20%)**—occur in the region of the endocardial cushion
- **Sinus venosus ASD (5%)**—in the sinus venosus septum
- **Coronary sinus ASD (very rare)**—in the region of ostium of coronary sinus
- **Vestibular ASD (extremely rare)**—in the region of the triangle of Koch above the septal tricuspid leaflet
- **Patent foramen ovale (PFO)**—normal fetal interatrial communication persisting beyond childhood.

INCIDENCE

Atrial septal defects account for 8–10% of congenital heart diseases (CHDs) in children. Male to female ratio is 1:2 in secundum defects and 1:1 in primum defects.

GENETIC FACTORS

Most defects are sporadic. The risk of CHD in infants born to a mother with ASD is 8–10%; mutations in regulatory genes or their target sarcomeric genes are reported in these children. Regulatory gene mutations in transcription factors NKX 2.5 (AD), TBX 5 in Holt–Oram syndrome (AD), familial ASD with AV nodal conduction delay (AD), TBX 20, *GATA 4* and *6* genes have been reported to be responsible for occurrence of ASD. Sarcomeric gene mutations (associated with cardiomyopathy) and missense mutation in alpha myosin heavy chain have also been identified in children with ASD. Syndromic associations with ASD include Down, Klinefelter, William, Kabuki, Goldenhar, Ellis-van Creveld syndromes and

Axenfeld-Rieger anomaly (glaucoma, dental anomalies, hernia and hypospadias). Maternal risk factors identified during pregnancy include diabetes, phenylketonuria, influenza, retinoids, nonsteroidal anti-inflammatory drugs (NSAIDs), antiepileptic drugs, thalidomide, smoking and alcohol.

ANATOMY

Secundum ASD It occurs as a single and rarely as multiple defects in the central part of fossa ovalis. It represents enlarged ostium secundum, caused by ectopic or excessive resorption of septum primum or deficient growth of septum secundum.

Primum ASD It occurs anteroinferior to fossa ovalis and guarded anteroinferiorly by the atrioventricular valves. They are invariably associated with cleft in the anterior mitral leaflet.

Sinus venosus defects These occur outside the margins of fossa ovalis, posterior to it. They are of two types. The most common is the superior vena cava (SVC) type defect, where the SVC orifice overrides the defect and is associated with anomalous drainage of right upper pulmonary vein to the right SVC. The rare right atrial type of sinus venosus defect is associated with anomalous drainage of right lower pulmonary vein into the RA and the inferior vena cava (IVC) orifice overrides the defect. This right atrial type of defect may be difficult to differentiate from a very large secundum ASD. Embryologically, the sinus venosus ASD occur due to unroofing of the right pulmonary veins causing their drainage into either SVC (in former) or RA (in later).

Coronary sinus ASD (called Raghbi's defect) is associated with complete or partial unroofing of the coronary sinus, resulting in shunting of left atrial blood through this unroofed coronary sinus into the RA through the enlarged ostium of the coronary sinus. This is often associated with persistent left SVC.

HEMODYNAMICS

Hemodynamics in Young Age

The persistence of high fetal pulmonary vascular resistance (FPVR) and fetal right ventricular hypertrophy limits the left to right shunt through ASD and hence children with ASD remain asymptomatic during this early period. With the gradual regression of FPVR and subsequent improvement in the capacitance of the elastic pulmonary artery and thinning of the right ventricle (RV) making it compliant and accommodative, the quantum of left to right shunt gradually increases resulting in increased pulmonary blood flow. The compliant RV tolerates volume overload well without rise of filling pressures. The capacitant pulmonary arterial bed accommodates high flows without increasing the pulmonary artery pressures. So, heart failure does not occur. Leftward shift of interventricular septum alters left ventricular geometry and causes mismatch between the relative sizes of the left ventricle (LV) and mitral valve leaflets. This leads to prolapse of the mitral leaflets and may lead to secondary mitral regurgitation. Repeated cuspal trauma leading to thickening and fibrosis of mitral leaflets increases the left to right shunt. Relentless increased pulmonary blood flow over many years eventually results in muscularization of the pulmonary arteriolar bed leading to late development of pulmonary arterial hypertension (PHT).

Hemodynamics in Later Childhood and Adulthood

The RV that efficiently manages the volume overload in early childhood, eventually fails to do so in later age and the right-sided filling pressures increases. This leads to congestive heart failure (CHF). Secondary tricuspid and pulmonary annular dilatation with regurgitation may further increase the right ventricular volumes.

Figures 1A and B (A) Cartoon illustration of interatrial septal surface of right with locations of superior vena cava (SVC), inferior vena cava (IVC), coronary sinus (CS), septal tricuspid leaflet (STL), ascending aorta (Ao) and triangle of Koch (TK); and (B) The locations of various types of ASD are indicated, (1) SVC type of sinus venosus defect, (2) IVC type of sinus venosus defect, (3) Secundum or fossa ovalis defect, (4) Primum ASD or partial atrioventricular canal defect, (5) Coronary sinus Raghbi's ASD and (6) Rarest vestibular ASD

Adult onset diseases such as systemic hypertension, atherosclerotic coronary ischemia and diabetic coronary microvascular disease cause left ventricular systolic and diastolic dysfunction and increase the left-sided filling pressures. This causes a secondary increase in the shunt in adult age. This additional increase of shunt tips the RV into CHF. In these older patients with elevated left ventricular end diastolic pressures, ASD closure will result in increase of left atrial and pulmonary venous pressures since they cannot pop-off their higher pressures into the right atria. This restrictive left ventricular physiology may worsen dyspnea after ASD closure. Enlarged right atrial size leads to atrial arrhythmias especially atrial fibrillation (AF). With advancing age, progressive vascular changes lead to PHT. The shunt reverses from right to left (Eisenmenger syndrome) usually after the fourth decade. They have a slow worsening of their symptoms and have a long natural history.

In a small minority of children with ASD, the progression of vascular changes in pulmonary circulation occurs disproportionately faster. In these patients, the pathology and progress of the PHT is akin to idiopathic PHT and the diagnosis of ASD becomes an incidental finding.

CLINICAL FEATURES

Symptoms

Most asymptomatic patients get detected on routine auscultation or incidental chest X-ray. Rarely, few infants may present with significant symptoms of growth failure and heart failure. The proposed reasons for this early symptomatology include rapid remodeling and thinning of the pulmonary vascular bed, failure of right ventricular myocardium to cope with volume overload, inappropriate increase of pulmonary artery pressures and underdiagnosed mitral valve abnormalities which augment the atrial shunt. These infants continue to grow slowly and remain symptomatic even after closure of the ASD.

Physical Findings

Jugular venous pressures are normal in early age, but with onset of heart failure or pulmonary hypertension, 'a' waves become prominent.

Precordium reveals prominent impulses in left parasternal border, subxiphoid area and pulsations in the left second intercostal space.

Heart sounds Tricuspid component of first heart sound is loud as the tricuspid valve leaflets are held far apart till end of diastole and there is wider excursion with onset of right ventricular systole. The classical hallmark of ASD is wide fixed splitting of the second heart sound. Increased right ventricular stroke volume caused by the shunted blood delays the right ventricular ejection and delays the pulmonary component of second sound. In the beginning of diastole, pulmonary valve closes at the point of the crossover of the falling right ventricular and pulmonary artery pressure curves. In patients with large ASD and low pulmonary artery impedance, the pulmonary valve continues to remain open even after the crossover of the pressure traces due to high capacitance of pulmonary arteries. This is called the long hangout interval. This widens the split, and is observed even in patients in pulmonary hypertension. Inspiratory increase of the systemic venous return augments right ventricular ejection and normally delays the pulmonary component of second sound. In patients with ASD, this inspiratory increase of systemic venous return will be compensated by a proportionate reduction in the left to right shunt and so the splitting remains fixed in different phases of respiration. The large pulmonary arteries have high capacitance to accept high pulmonary blood flows. During inspiration, there is no further increase of the pulmonary capacitance to allow higher flows. This also fixes the split. Even in

severe pulmonary hypertension, the associated right ventricular systolic dysfunction delays it and so the split remains wider.

Murmurs Flow systolic murmurs in pulmonary area (may very rarely lead to thrill in torrential shunts, or when associated with mild valvar pulmonary stenosis) and flow mid-diastolic murmurs in tricuspid area will be heard on auscultation. Rapid right ventricular diastolic filling leads to right ventricular third heart sound. PHT in later age leads to high frequency pulmonary early diastolic (Graham-Steell) murmur due to pulmonary regurgitation or left lower sternal pansystolic murmur due to tricuspid regurgitation.

Pulse Oximetry

Typically, oxygen saturations are normal. Hypoxia may be due to tricuspid valve hypoplasia or severe tricuspid regurgitation, right ventricular hypoplasia, pulmonary stenosis at any level or Eisenmenger syndrome. In some patients, it may be due to streaming of IVC blood in a right atrial form of sinus venosus defect or prominent Eustachian valve guarding the IVC orifice. It may also result from unroofed coronary sinus. Contrast echocardiogram with agitated saline will demonstrate occurrence of bubbles in the left-sided cardiac chambers and show right to left shunt.

DIAGNOSIS

Chest X-ray

Findings include cardiomegaly, right atrial enlargement, dilated main pulmonary artery segment, inconspicuous aortic knuckle and plethoric lung fields where increased vascular markings extend to the peripheries (**Figs 2A and B**). The dilated RV lifts the cardiac apex from the left dome of the diaphragm at the left cardiophrenic angle. The retrosternal radiolucent space on a lateral view is obliterated. With onset of pulmonary vascular disease, peripheral pulmonary vascular markings get pruned but central pulmonary arteries get markedly dilated. The lower part of right SVC is dilated in SVC type defects.

Electrocardiogram

Right ventricular enlargement delays activation of the right ventricular outflow tract causing rsR' pattern in V1 (**Figs 3A to C**). In older patients, right atrial enlargement and right axis deviation of QRS axis occurs. Slurring of QRS waves in inferior leads called *crochetage sign* is seen very often. P axis is deviated leftwards in SVC type of sinus venosus defects. Primum ASDs show leftward QRS axis with counterclockwise loop, shown as deep *q* waves in I and aVL. 5% of secundum and sinus venosus defects may also have left axis deviation. Older patients may show sinus nodal disease, junctional escape rhythm, atrial ectopics, atrial arrhythmias including fibrillation. Onset of pulmonary hypertension leads to further right axis deviation of QRS axis, occurrence of *q* waves in V1 and increase of height of R' in V1. Certain familial ASD shows first or second degree AV nodal block. Respiratory sinus arrhythmia is almost never seen.

Echocardiogram

Location of ASD in the atrial septum differentiates the different forms of ASD (**Figs 4A to D**). Important common associations include anomalous pulmonary venous drainage (seen in 10%), mitral valve regurgitation (10%) and valvar pulmonary stenosis (10%). Doppler interrogation confirms direction of left to right color flow across the ASD, gives assessment of severity of pulmonary hypertension by tricuspid regurgitation jet, detects mitral regurgitation and pulmonary stenosis. Echocardiography also assesses the margins of the defect and identifies the defects amenable for device closure in the present era of nonsurgical interventions for most secundum defects.

Figures 2A and B Chest X-ray in ASD. (A) In large ASD with increased pulmonary blood flows, there is cardiomegaly, prominent main pulmonary artery segment, dilated right and left pulmonary artery shadows in both hilum. The pulmonary vessels can be tracked to the peripheral one-third of the lung fields as shown by the arrow and (B) Once pulmonary vascular occlusive disease occurs (Eisenmenger), the peripheries of the lungs get pruned of the blood vessels, the main pulmonary artery and hilar right and left pulmonary artery get aneurysmally dilated. The cardiomegaly increases further due to dilatation of right-sided chambers secondary to tricuspid and pulmonary regurgitation

Figures 3A to C ECG in ASD. (A) In secundum ASD, frontal QRS axis is deviated minimally to the right and there is rsr' pattern in lead V1; (B) Primum ASD characteristically demonstrates left axis deviation and counterclockwise looping shown as deep q waves in leads I and aVL and (C) SVC type of sinus venosus ASD may demonstrate leftward deviation of P axis from 0° to -30°

Figures 4A to D Echocardiogram in different types of ASD. (A) *Subxiphoid view*: Large secundum ASD in mid-portion of fossa ovalis shown in arrow; (B) *Apical view* demonstrates dilated right atrium (RA) and right ventricle (RV) in comparison to (C) Left atrium (LA) and left ventricle (LV). In contrast to secundum ASD (A), a sinus venosus ASD of SVC type occupies the posterosuperior part of septum on subxiphoid view and there is override of the superior vena caval orifice (SVC) into the right atrium and (D) Ostium primum ASD shown in an apical view, occupies the anteroinferior part of the septum and bounded by the atrioventricular valves

Cardiac Catheterization

Oximetry run from samples drawn from vena cava to pulmonary artery shows 7–10% step up in oxygen saturations at the level of RA. Other causes of step up in RA include Gerbode ventricular septal defect (VSD), VSD with tricuspid regurgitation, coronary fistula into RA, partial anomalous pulmonary venous drainage to RA and ruptured aortic sinus into RA. The shunt ratio (Q_p/Q_s) calculated with oximetry more than 1.5:1 indicates significant shunt and need for treatment. In patients with severe pulmonary hypertension, vascular resistances are calculated by pulmonary artery pressure measurements. If the pulmonary vascular resistance index is more than 8 Wood units, even after oxygen or other pulmonary vasodilators such as nitric oxide, patients are considered inoperable.

NATURAL HISTORY OF UNTREATED ASD

Most defects below 5 mm in neonates and infants close spontaneously, but defects larger than 8 mm seldom close. Apart

from 5% of young infants who present with severe heart failure, most children are asymptomatic. 25% of patients with ASD die by 30 years, 50% by 37 years, 75% by 50 years and 90% by 60 years. 14% of young adults develop progressive pulmonary hypertension and 6% develop Eisenmenger syndrome. 50% of patients aged 40 years have paroxysmal or permanent AF. Most adults develop heart failure.

TREATMENT

Medical Management

Asymptomatic children need no medications. The small subset of infants who present with severe heart failure and right ventricular dysfunction may require diuretics and digitalis. Patients with Eisenmenger syndrome may get symptom relief with pulmonary vasodilators namely sildenafil or bosentan. Amiodarone is given for medical cardioversion of AF and to prevent recurrences; digoxin controls ventricular rates in AF.

Figure 5 Lateral view chest X-ray after nonsurgical device closure of ASD with nitinol wiremesh occluder device demonstrating the two discs, the posterior left atrial disc is closer to spine

Surgical Correction

Open heart surgical correction of primum defects and sinus venosus defects are done at an appropriate age between 1 year and 5 years. Primum ASD with severe mitral regurgitation from cleft of anterior mitral leaflet may benefit from early surgery. Surgery of sinus venosus defect is often deferred till 4–5 years since surgical baffling of the right upper pulmonary veins to the LA in early ages may compromise the lumen of SVC RA junction. Most patients with secundum ASD are amenable for nonsurgical transcatheter management in current era, except very large defects with deficient margins. Instead of full sternotomy for surgical access, cosmetic approaches in recent times include ministernotomy (small midline incision), right anterolateral thoracotomy (inframammary incision in postmenarchal girls), right posterolateral thoracotomy (below the scapular line), minimally invasive cardiac surgery (using femorofemoral cardiopulmonary bypass and small chest incisions) and robotic surgery. These innovations limit the size of the surgical incisions markedly.

Nonsurgical Interventions

Currently, most secundum defects with adequate margins on echocardiogram are closed in cardiac catheterization laboratory with nitinol (nickel-titanium alloy) wire mesh occluder devices through femoral venous route under echocardiographic and fluoroscopic guidance (**Fig. 5**). This avoids cardiopulmonary bypass related complications, surgical scars, blood transfusions and mechanical ventilation. The hospital stay is short and recovery is early.

After the device closure, antiplatelet dose of aspirin is given for 6–12 months till complete endothelialization of the device. Complications such as device embolization, thrombus formation,

cardiac perforations and infection are extremely rare. In patients with severe pulmonary hypertension or restrictive left ventricular physiology, fenestrated devices allow a small flow through the atrial septum instead of a complete closure.

PATENT FORAMEN OVALE

While 25–33% of normal adults have been shown to have a probe patency of foramen ovale, a small right to left shunt with paradoxical embolism across PFO may lead to few cryptogenic strokes or transient ischemic attacks. PFO is also implicated in migraine with aura, decompression sickness, diver's illness and platypnea-orthodeoxia syndromes. In these patients, a right to left shunt is documented by agitated saline injection contrast echocardiography or transcranial Doppler study. Device closure of PFO is carried out in catheterization laboratory from femoral venous access.

IN A NUTSHELL

1. Most atrial septal defects are secundum ASD (75%) and occur in central part of atrial septum in fossa ovalis; 20% are primum ASD (20%) and occur in the region of the endocardial cushion.
2. The classical hallmark of ASD is wide fixed splitting of the second heart sound. CHF occurs only in later childhood. The RV that efficiently manages the volume overload in early childhood, eventually fails to do so in later age and the right-sided filling pressures increases.
3. Enlarged right atrial size leads to atrial arrhythmias especially AF. With advancing age, progressive vascular changes lead to pulmonary hypertension. The shunt reverses from right to left (Eisenmenger syndrome) usually after the fourth decade.
4. Most children are asymptomatic. 25% of patients with ASD die by 30 years, 50% by 37 years, 75% by 50 years and 90% by 60 years. Half of patients aged 40 years have paroxysmal or permanent atrial fibrillation. Most adults develop heart failure.
5. Open heart surgical correction of primum defects and sinus venosus defects are done at an appropriate age between 1 year and 5 years. Most patients with secundum ASD are amenable for nonsurgical transcatheter management in current era, except very large defects with deficient margins.

Chapter 40.14

Atrioventricular Septal Defects

Snehal Kulkarni, Tanuja Karande

Atrioventricular septal defects (AVSD) are abnormalities of the atrioventricular septum and of the atrioventricular valves. They can also be identified as the atrioventricular canal defects and endocardial cushion defects.

As these children present with severe heart failure in early infancy, the possibility of AVSD should be kept in mind while evaluating a symptomatic infant with congestive heart failure. After confirming the diagnosis with echocardiography, these children need to be screened for possible chromosomal anomalies such as trisomy 21. They need aggressive medical management for control of heart failure. Complete recovery is possible with timely diagnosis and surgical repair.

INCIDENCE

Incidence of AVSD varies from 1.4% to 10.8% (4–5%) of all congenital heart defects. This constitutes 0.19 per 1,000 livebirths.

ASSOCIATIONS

Complete AVSD is the most common association with Down syndrome seen in approximately 40–50% of children. They are also more likely to have associated tetralogy of Fallot. Complete AVSDs also occur in patients with heterotaxy syndromes (more common with asplenia than with polysplenia). Common atrium has been associated with Ellis-van Creveld syndrome.

CLASSIFICATION (FIG. 1)

Atrioventricular septal defects either can be partial or complete depending upon their morphological characteristics. Primum atrial septal defect (ASD) is always a part of AVSD and there are two separate mitral and tricuspid valve annuli. The mitral valve usually has a cleft and there is evidence of mitral regurgitation through the cleft. When there is a presence of additional small inlet VSD, it is classified as *transitional AVSD*. The *complete AVSD* has a common atrioventricular valve with a single AV valve annulus. Primum ASD and a large inlet VSD are always present and they are contiguous with each other. *Intermediate AVSD* is very similar to complete AVSD except it has two separate right and left AV valve orifices, but the AV valve annulus is common.

A practical mode of classification depending upon the size of ventricular chambers has practical importance. AVSD is divided

Partial AVSD-primum ASD with separate mitral and tricuspid annuli

Complete AVSD with primum ASD, inlet VSD, and common valve

Transitional

Partial

Complete

Intermediate

Figure 1 Morphological classification of atrioventricular septal defect (AVSD)

into *balanced* and *unbalanced* AVSD, if either of the ventricle is hypoplastic. This classification depends upon the attachment of AV valves to the respective ventricles. If one of the ventricles is very small, complete two ventricular repair is not possible. These children eventually undergo univentricular palliation in stages.

PATHOLOGY

Ostium primum ASD is commonly seen in patients with partial AVSD. There is left-to-right shunt across the ASD and there is evidence of mitral or tricuspid valve insufficiency through the clefts of the respective valves. Due to large shunt across the interatrial septal defect, pulmonary arterial pressures are mildly elevated. The physiology of this lesion is therefore similar to that of a large ostium secundum ASD.

As there is a large ASD and a large VSD in complete AVSDs, the left to right shunt occurs at both the levels. Because of excessive pulmonary blood flows pulmonary arterial hypertension is common. In addition to the excessive pulmonary blood flow, the immaturity of lung tissue especially in children with Down syndrome, make them susceptible to increased pulmonary vascular resistance at an early age (Eisenmenger physiology). The ventricles become dilated, if there is AV valve insufficiency.

CLINICAL MANIFESTATIONS

The degree of shunt and AV valve regurgitation determine the clinical features. Virtually, all patients with complete AVSD are symptomatic by 2–6 months of age. Failure to thrive with history of poor feeding, excessive sweating, easy fatigability, fast breathing, chest retractions and recurrent pneumonias occur early in infancy as these shunts have significantly increased pulmonary blood flow. The symptoms worsen in the presence of severe mitral insufficiency. If these symptoms do not develop early, the clinician should suspect premature development of pulmonary vascular obstructive disease.

An uncomplicated primum ASD often is discovered in young children when echocardiography is performed to investigate a murmur. The murmur has typical systolic ejection qualities and is best heard over the upper left sternal border with radiation to the lung fields. The second heart sound is widely split and fixed during respiration. A holosystolic murmur owing to mitral regurgitation through the cleft may be heard at the apex. A low-pitched mid-diastolic murmur can be present. This murmur is secondary to increased flow through the mitral valve orifice.

INVESTIGATIONS

Fetal echocardiography The four chamber view in fetal echocardiography can identify and diagnose AVSD easily and

should be recommended, especially if other anomalies are suggestive of Down syndrome; the parents should be counseled accordingly.

Electrocardiogram (ECG) changes are shown in **Figure 2** and summarized in **Table 1**.

Echocardiography The diagnosis of this anomaly can be done with two-dimensional echocardiography. The apical four-chamber imaging plane clearly visualizes the internal crux. The primum ASD can be diagnosed with apical four chamber view. Usually, the lower atrial septum is absent. The atrioventricular valves are displaced toward the ventricles, with the septal portions inserting at the same level onto the crest of the ventricular septum. The most common abnormality, a cleft, is best visualized from the parasternal and subcostal short-axis imaging planes. In the normal heart, the aortic valve is wedged between the mitral and tricuspid annuli. In AVSD, the aortic valve is displaced anteriorly. This anterior displacement creates an elongated, so-called gooseneck deformity of the left ventricular outflow tract (LVOT). LVOT obstruction may occur in all forms of AVSD (**Figs 3A and B**).

TREATMENT

Surgical correction at an early age, preferably before 6 months of age before the development of pulmonary vascular resistance is undertaken. Medical therapy with diuretics, angiotensin converting enzyme (ACE) inhibitors and digoxin serves to stabilize the patients with large shunt and cardiac failure until surgery.

Table 1 Electrocardiogram (ECG) in atrioventricular septal defect (AVSD)

<i>Superior orientation of the mean frontal QRS axis with left axis deviation (LAD)</i>	
1. Mean QRS axis in the frontal plane (range): -30° to -120°	
Partial AVSD	: Axis direction: -30° and -90°
Complete AVSD	: -90° to -120°
Down syndrome (AVSD)	: Extreme left axis deviation
2. Counterclockwise inscription of the superiorly oriented QRS vector loop. Q wave in leads I and aVL	
3. Biventricular hypertrophy (BVH) or isolated right ventricular hypertrophy (RVH)	
4. Incomplete right bundle branch block—rSR' pattern in leads V3R and V1)	
5. Normal or tall P waves	
6. Sinus rhythm with prolongation of the P-R interval (18–70% of AVSD) due to increased intra-atrial conduction time from high right atrium to low septal right atrium	

Figure 2 Electrocardiogram (ECG) of a 3-month-old infant with superior axis and right ventricular hypertrophy (RVH)

Figures 3A and B Elongated left ventricular outflow tract (LVOT) simulating a goose neck deformity

In complete AVSD, repair must be done very early, as they have a tendency to develop pulmonary vascular resistance at an earlier age. Surgical correction aims at closure of all the shunts, maintenance of competent AV valves and repair of associated defects. They have near normal cardiac status after surgery. A small percentage of patients may need another surgery for mitral valve repair.

Most of these children become inoperable after 1 year of life due to elevated pulmonary vascular resistance and have a tendency to develop Eisenmenger syndrome (ES) early. Once they develop irreversible pulmonary vascular disease and ES, the natural survival is limited.

The surgical correction of partial AVSD aims at ASD closure and repair of AV valves at about 2–3 years of age. As these lesions behave more such as large ASDs, these children are completely normal after surgical repair. These patients can develop complete AV block, mitral regurgitation and LVOT obstruction after surgery.

IN A NUTSHELL

1. Atrioventricular septal defects are abnormalities of the atrioventricular septum and of the atrioventricular valves. They are also identified as atrioventricular canal defects and endocardial cushion defects.
2. Possibility of complete AVSD should be strongly considered in small infants who present with severe congestive heart failure in early infancy, especially in children with Down syndrome.
3. They should be stabilized initially with antifailure line of treatment. Echocardiography is the key to the diagnosis. Timely diagnosis and early surgical repair before 6 months is very important.

Chapter 40.15

Patent Ductus Arteriosus

K Sivakumar

Patent ductus arteriosus (PDA) refers to a communication between the proximal descending thoracic aorta and the main pulmonary artery. Being essential to be patent in fetal life, it closes within the first few hours to days in all neonates after birth. Persistent patency of the ductus arteriosus (DA) leads to a wide range of hemodynamically significant problems and sometimes even fatal complications such as bacterial endarteritis in postnatal life.

ANATOMY

In most patients with left aortic arch, ductus communication originates from the descending thoracic aorta about 5–10 mm distal to origin of the left subclavian artery and ends in the pulmonary artery confluence. DA starts closing within few hours after birth from the pulmonary end towards the aorta thus resulting in a conical narrow pulmonary end and a wider aortic end (Type A ductus). However, PDA may have varying shapes, some are narrow at aortic end (Type B), some are tubular (Type C), some have mid-ductal constriction (Type D) and the rest have bizarre shapes

(Type E). The significance of its shape gains importance only during planning for interventional duct closure (**Fig. 1**).

Rarely in patients with left arch, the ductus may arise from the right subclavian artery to get connected to the right pulmonary artery. Bilateral ductus are even rarer. In patients with right aortic arch, ductus are common on the left side between left subclavian artery and left pulmonary artery (**Fig. 2**); right side ductus connecting right descending aorta to right pulmonary artery is rarer.

HEMODYNAMICS

Normal Ductal Closure after Birth

Within few hours after birth, the increasing PO_2 of aortic blood causes medial smooth muscle constriction and migration of smooth muscle into the inner wall of the ductus leading to *functional closure*. Infolding of endothelium, disruption of internal elastic lamina, subintimal proliferation, hemorrhage and necrotic edema facilitate later *anatomical closure*. Further, connective tissue proliferation with ensuing fibrosis converts the duct into ligamentum arteriosum. Besides oxygen, the other constricting factors include acetyl choline, catecholamines and bradykinin. Cessation of prostaglandin (PG) production by ductal tissue, withdrawal of placental PG after cord clamp and metabolism of circulating PG by lungs cause constriction of the duct. Preterm ductus are less responsive than term ductus to oxygen and

Figure 1 Aortogram in lateral view showing different morphological shapes of PDA: Type A PDA has conical shape with wide aortic end and narrow pulmonary artery end. Type B PDA has wide aortic end and narrow pulmonary artery end. Type C PDA is tubular and Type D PDA has mid-ductal constriction. The classification of ductus by its shape is important in deciding about the method of transcatheter closure
Abbreviations: Ao, aorta; PA, pulmonary artery.

Figure 2 Right aortic arch with left-sided PDA. In patients with right aortic arch, the first arch branch is left innominate artery. PDA arises from either the left innominate artery or left subclavian artery in these patients. It is important to recognize the side of aortic arch before surgical correction

Abbreviations: Ao, aorta; RAA, right aortic arch; Lt inn, left innominate artery; PA, pulmonary artery.

other vasoconstrictors, but are also more sensitive to PG. Premature lungs do not effectively metabolize the PG. So, preterm ductus continues to remain patent for longer period than term babies.

Hemodynamics in Term Babies

In term neonates, the fetal pulmonary resistance continues to remain high for few weeks and this prevents a large left to right shunt. After 1–3 months, with progressive fall of pulmonary vascular resistance (PVR), the patients become symptomatic. The compensatory mechanisms include Frank Starling mechanism in a volume overloaded stretched left ventricular myocardial fiber, progressive left ventricular myocardial hypertrophy, heightened sympathetic activity, all of which increase the left ventricular contractility. This also leads to tachycardia and increased sweating. A large run-off into the pulmonary artery will result in very low aortic diastolic pressure. Tachycardia will also reduce the diastolic period during which coronaries get perfused. This combination of low aortic diastolic pressures, high left ventricular end diastolic pressures and short diastolic period contribute to reduced myocardial perfusion. Prolonged exposure of pulmonary vascular bed to aortic pressures lead to permanent vascular changes, pulmonary arterial hypertension (PAH) and eventually tends to cause reversal of shunt from pulmonary artery to aorta. This results in differential cyanosis with lower limbs more cyanosed than right upper limb, a unique diagnostic feature of ductus with Eisenmenger syndrome. These patients have more exercise induced leg fatigue but less dyspneic compared to other causes of Eisenmenger syndrome. As the ascending aortic saturations are normal, respiratory center and carotid body chemoreceptor are not stimulated.

Hemodynamics in Preterm Babies

Inadequately developed pulmonary arteriolar musculature causes rapid fall of the fetal PVR in preterm. A large shunt increases the pulmonary venous return and increases the left ventricular preload. Preterm left ventricle, with its limited and fewer contractile myocardial architectural components, inadequately responds by Frank-Starling mechanism. Incomplete sympathetic innervation,

low circulating calcium levels, low effective coronary perfusion during diastole in PDA, higher fetal hemoglobin levels associated with low 2,3-diphosphoglycerate (2,3DPG) and more pronounced physiological anemia seen in prematurity reducing the oxygen delivery further to the tissues are all responsible jointly for the onset of early symptomatic heart failure in preterms.

INCIDENCE

In full-term infants, PDA account for 5–10% of all congenital heart defects. Male : female ratio is 1:2. Incidence is six times high in high altitudes. Genetic syndromes associated with PDA are rare, and include Down, Rubinstein-Taybi (broad thumbs, big toe) and Char syndromes (triangular facies with ptosis, short philtrum and patulous lips, abnormal fifth finger, supernumerary nipple). Maternal rubella infection is a known teratogen in the first trimester of pregnancy. It is important to realize that PDA in term babies is a structural abnormality, but in preterms, it is just a physiological developmental problem. In preterms, PDA occurs in 8 out of 1,000 babies. The incidence is proportional to the degree of prematurity. It is 45% in preterms weighing less than 1,750 g at birth, 80% in preterms with less than 1,250 g weight and almost invariably seen in all preterms with less than 1,000 g birthweight when associated with lung disease.

CLINICAL FEATURES

Symptomatology

The diameter and length of the duct, relative resistances of the pulmonary and systemic arterial bed determine the degree of shunt from aorta to the pulmonary artery. Narrower and longer ducts offer more resistance to flow of blood. Large window such as ducts with short lengths will transmit entire aortic pressures to pulmonary arteries and lead to elevated pulmonary artery pressures. Symptoms in PDA depend on the degree of shunt and the myocardial ability to handle the resulting volume overload. While gross heart failure and recurrent pneumonias are seen in very large ductus, moderate ductus causes mild growth retardation and effort intolerance. The symptoms are minimal as long as the myocardial hypertrophy compensates for the volume overload without undue increase of left ventricular end diastolic pressures.

Examination Findings

Peripheral pulses—radials, dorsalis pedis, are bounding with wide pulse pressures once the left to right shunt gets established after fall of the neonatal PVR. Pulse rates are higher in infants with heart failure, who tire out easily, sweat profusely and thrive poorly. Precordium is hyperkinetic, proportionate to the left ventricular volume overload. The characteristic auscultatory finding is Gibson's continuous murmur, characterized by late systolic peaking and continuation through the second sound into the diastole. There are multiple crackling eddy sounds in the murmur, which vary from beat to beat and give the murmur a machinery quality. This is absent in most other causes of continuous murmurs such as venous hum, coronary arteriovenous fistulae and ruptured sinus of Valsalva aneurysm. These eddy sounds are caused by coalition of two jets hitting in opposing direction, one antegrade from pulmonary outflow and other retrograde from duct into the main pulmonary artery. In infants with gross heart failure due to very large PDA, murmur may be present only in systole. The masking of the diastolic component of the murmur is due to very low flows from aorta to pulmonary artery in diastole due to complete equalization of diastolic pressures between aorta and pulmonary artery. Second sound may be paradoxically split due to prolonged left ventricular ejection, but is difficult to appreciate in the continuous murmur. In Eisenmenger syndrome, the split becomes closer, but again widens, if right ventricle fails later.

NATURAL HISTORY

Ductus arteriosus seldom closes beyond early infancy. Spontaneous closure in later age may be due to endocarditis or thrombus. Sometimes a closed ductus may reopen due to rupture of valve such as membrane or dissection of the duct. Moderate to large ductus in term babies become symptomatic after 4–6 weeks of life once the fetal PVR falls. If the left ventricle fails to cope with the volume overload caused by the large shunt, the infants become very sick to need urgent interventions. Dilated left atrium may obstruct left lung airway and cause hyperinflation or collapse of the lungs and lead to pneumonia. After 3–6 months, progressive left ventricular myocardial hypertrophy causes compensation of the heart failure and symptoms tend to improve.

In untreated large ductus, beyond 18 months of age, pulmonary vascular changes may begin to appear and symptoms slowly subside. Differential cyanosis starts to appear initially on exertion and later at rest. Infective endarteritis may be diagnosed with vegetations in the pulmonary end of the duct. Ductal aneurysms may sometimes be incidentally detected or associated with hoarse voice secondary to recurrent laryngeal neuroparaxia. Aneurysms may rupture, dissect, form thrombus that embolize, get infected, compress left pulmonary artery or left bronchus, and rarely present with hemoptysis or hematemesis. Calcification may occur in adult life, pose problems for surgical ligation and division. Sudden deaths in adults are due to rupture or dissection.

DIAGNOSIS

Chest X-ray

Cardiomegaly, dilated main pulmonary artery segment, increased lung vascularity are proportional to the shunt. Unlike ventricular septal defect, aortic knuckle will also be prominent (**Figs 3A and B**). Young infants with heart failure show pulmonary venous hypertension, interstitial opacities causing hilar haze. Dilated left atrium may lead to collapse or hyperinflation of the lower lobe of left lung. Rare findings include ductal aneurysm causing abnormal bulge on left heart border and ductal calcification in adults.

Electrocardiogram

Mean QRS axis is normal, except in rubella syndrome where superiorly directed QRS axis may be noted. Left ventricular forces

may dominate and lead to deep Q waves in V6 with tall upright T waves. Left atrial enlargement may be seen. Pulmonary vascular disease may shift the QRS axis to right and lead to prominent right ventricular forces and right atrial enlargement. PR segment is prolonged in 10–20% patients.

Echocardiogram

Most important utility of echocardiogram in a child with classical continuous murmur of PDA is to exclude a duct dependent lesion such as pulmonary atresia where a duct should never be closed. The hemodynamics of the PDA will be shown by left atrial and ventricular enlargement, gradient across the PDA on continuous Doppler trace, flow reversal in abdominal aorta in diastole. Anatomy of the PDA, its size at aortic and pulmonary end, its shape, absence of coexistent posterior ductal shelf (causing coarctation of aorta) are important findings to plan interventional nonsurgical transcatheter PDA closure (**Figs 4A and B**).

Figures 4A and B (A) Echocardiography in PDA in ductal view shows large tubular communication shown by arrow between the descending aorta (Ao) and pulmonary artery (PA) and (B) Color Doppler flows across the PDA from aorta to pulmonary artery

Figures 3A and B Chest X-ray in PDA. In large ducts with large left to right shunt (A), there is cardiomegaly, dilated main pulmonary artery segment, plethoric lung fields, dilated aortic knuckle. When the pulmonary vascular resistance increases to lead to reversal of shunt as in Eisenmenger syndrome (B), there is more dilatation of the central pulmonary arteries and pruning of the vasculature in the peripheral one-third of the lung fields

Cardiac Catheterization Hemodynamics

The utility of catheterization is resorted to assess the hemodynamic characteristics of the shunt in patients with features of high PVR (Table 1).

TREATMENT

Medical Management of Preterm PDA

Urgent treatment is resorted to, if there is respiratory distress, apnea, heart failure, splanchnic ischemia and necrotizing enterocolitis due to aortic run-off. Packed cell transfusion to improve oxygen carrying capacity; it reduces the HbF concentration and improves tissue oxygen delivery. Other steps include sodium and fluid restriction, diuretics and dopamine for inotropic effect.

Pharmacological closure Indomethacin orally or intravenously at dose of 0.2 mg/kg is given unless, there is severe renal failure, bleeding or manifest necrotizing enterocolitis. Alternatives to indomethacin are ibuprofen (less incidence of renal failure), oral propranolol and oral paracetamol. In patients who fail these medications, surgical ligation after thoracotomy, thoracoscopic clipping and transcatheter device closure are done.

Management of Term PDA

In symptomatic PDA, early treatment is warranted. In severe heart failure, stabilization with diuretics, inotropes and ventilation may be needed. Definitive treatment involves transcatheter closure or surgical closure.

Transcatheter closure is done through femoral artery or venous access with platinum embolization coils with Dacron fibers or ductus occluder devices, which are nickel-titanium alloy wire mesh occluders with polyester fabric inside the mesh (Figs 5A and B).

Table 1 Management decision for PDA based on cardiac catheterization hemodynamics

<p>Contraindications for ductus closure</p> <ul style="list-style-type: none"> Severe PAH with the following catheter hemodynamic data 	<ul style="list-style-type: none"> Step down of oxygen saturations from ascending aorta to descending aorta is more than 2% Oxygen saturations in femoral artery is below 92% irrespective of the ascending aortic saturations Pulmonary vascular resistance exceeds 8 Wood units No substantial improvement of vascular resistance on oxygen or vasodilators such as nitric oxide and No discernible fall in pulmonary artery pressures with test balloon occlusion of ductus
<p>Justifiable indications for ductus closure</p>	<ul style="list-style-type: none"> Step-up from right ventricle to pulmonary artery over 5% Qp/Qs ratio of more than 1.5
<p>There are some practical difficulties in oximetry since the stream of blood from aorta through the duct may stream into one or the other pulmonary artery.</p>	

Abbreviation: PAH, pulmonary arterial hypertension.

Surgical treatment is done with ligation through left thoracotomy (carries risk of recanalization), triple ligation or ligation and division (eliminates risk of recanalization) or thoracoscopic clipping of ductus. PDA surgical closure is often performed by closed heart surgery; but some calcified ductus in adults may need surgery on cardiopulmonary bypass. In hypertensive ductus with elevated PVR, medical therapy with sildenafil, bosentan is indicated.

Figures 5A and B Interventional closure of PDA in cardiac catheterization laboratory can be done without surgical incisions through femoral venous or arterial cannulation. They are done with coils (A) or nitinol occluder devices (B)

IN A NUTSHELL

1. Patent ductus arteriosus is a structural abnormality in term babies, but a physiological developmental disadvantage in preterms.
2. Shunting across PDA depends on size of the duct, relative differences between the pulmonary and systemic vascular resistances.
3. Continuous murmur peaking around the second sound with eddy sounds is hallmark of PDA with large left to right shunt.
4. Spontaneous closure of PDA in term babies is very rare and will need closure.
5. Most preterm ducts are managed by conservative medical therapy.
6. Nonsurgical closure of PDA has emerged to be safer and more attractive alternative to surgery.
7. Late problems of uncorrected PDA include pulmonary hypertension, shunt reversal, ductal calcification, aneurysm and endocarditis.

Chapter 40.16

Anomalous Left Coronary Artery from Pulmonary Artery, Coronary Arterial Fistula and Ruptured Sinus of Valsalva

MS Ranjith

ANOMALOUS LEFT CORONARY ARTERY FROM PULMONARY ARTERY

Anomalous left coronary artery from pulmonary artery (ALCAPA) is a rare but important anomaly as it is treatable and long-term outlook is excellent if recognized and referred early for surgical repair. Incidence is 1:250 to 1:400 of all congenital cardiac defects with a male preponderance. ALCAPA is usually an isolated anomaly although rarely symptoms may be prevented by presence of a patent arterial duct or a ventricular septal defect.

Pathophysiology

In fetal life there are no effects; postnatally in the first few weeks, pulmonary artery (PA) pressures remain elevated with some admixture at the oval fossa and ductal levels, therefore increased extraction by the myocardium compensates. As PA pressure falls the left coronary artery (LCA) is perfused by desaturated blood at low pressures. Left ventricle (LV) with huge oxygen demand becomes ischemic. LV function becomes progressively impaired. Simultaneously collaterals develop from the right coronary artery (RCA) which arises normally from the aorta, to the LCA. This determines the presentation, as ischemic damage varies depending on the collateralization. Therefore, adults may present with a perfect set of collaterals and good LV function, while young infants may have poor collaterals and severe ischemic damage.

Hemodynamics

The RCA enlarges as collaterals develop while the LCA remains small. With extensive collaterals, the LV remains well-perfused while with poorly developed collaterals, the LV becomes ischemic, dilated, dilated and fibrotic. Mitral regurgitation develops both due to annular enlargement as the LV dilates and due to papillary muscle involvement in the ischemic process. Left atrium then enlarges with increase in pressures leading to pulmonary venous congestion.

Clinical Features

Infants may present with symptoms of congestive cardiac failure (CCF). Others have incidental detection of cardiomegaly on the chest X-ray (CXR). Murmur of mitral regurgitation or a gallop rhythm may be noted. Presentation as a *dilated cardiomyopathy* is frequent and an electrocardiogram (ECG), CXR or echocardiogram may reveal the diagnosis. Some infants present with the typical *bland white and garland* syndrome of ischemic angina episodes brought about when feeding, stress or defecation; the infant is then severely distressed with grunt, diaphoresis, distress and crying. These symptoms are mistaken for a colic or reflux.

Features of CCF are evident in some with respiratory distress, hepatomegaly and mitral regurgitation murmur or a gallop rhythm and an apical mid-diastolic rumble. Pulses are small volume with tachycardia. Apex is displaced down and out. Sometimes an

angina episode is witnessed but rarely recognized. The older child with good collaterals may have normal cardiac findings. Excessive collaterals may cause a continuous murmur resembling a patent arterial duct.

Investigations

Electrocardiogram Sinus tachycardia with ventricular ectopic beats, ventricular tachycardia and pathologic Q waves as well as ST segment and T wave abnormalities are seen in leads I, AVL, V5, V6 typical of anteroseptal myocardial infarction in sick infants with CCF. In some the ECG changes evolve with time. ECG may not be normal but may not be diagnostic on occasion. Older child with good collaterals may have a normal ECG.

Chest X-ray The sick infant may have cardiomegaly in varying degrees depending on extent of infarction and mitral regurgitation with left atrial enlargement and pulmonary venous congestion. The older child with good collaterals may have a normal CXR.

Echocardiography and Doppler In sick infants, left ventricular dilatation with poor contractility and varying degrees of mitral regurgitation is noted. Often misdiagnosed as dilated cardiomyopathy if the echocardiographer does not pay attention to the coronary arteries. Careful evaluation will demonstrate a dilated RCA and the LCA origin from the PA, often with reverse flow on color from the LCA to the PA.

Others Thallium 201 scintigraphy shows *cold areas* in affected myocardium, but is nonspecific and can occur in cardiomyopathy. Cardiac catheterization is seldom required unless ECG is atypical and echocardiogram inconclusive especially in the older child. Selective right coronary angiogram clearly demonstrates the left coronary artery filling from collaterals arising from the RCA, and often filling the PA. Computed tomography [(CT) angiography] is a better noninvasive alternative in this setting.

Natural History

Left untreated, some will stabilize with collateral development and survive to adult life to develop symptoms then but overall outlook is poor with death due to arrhythmia, CCF, cardiogenic shock in a majority.

Management

Medical management is to stabilize the child for surgery with inotropic support and afterload reduction using nitroglycerin. Digoxin is best avoided due to arrhythmogenicity. Morphine for pain and anxiety, ventilation and paralysis are required for the very sick.

Cornerstone of treatment is surgery. Early surgery at diagnosis offers the best prospect for the patient. Early procedures included ligation of the left coronary artery, internal mammary artery or subclavian artery graft. These are obsolete now. Direct reimplantation of the LCA from the PA to the aorta with a button of PA around the origin, is the modality of choice. In some instances of difficult coronary transfer, the Takeuchi procedure is applied; here an aortopulmonary window is created and a baffle used in the PA to direct aortic blood to the LCA. The sickest infants with severe LV dysfunction often require postoperative support with ventricular assist devices.

CORONARY ARTERY FISTULA

These are distal communications from the coronary artery, usually the right coronary artery (RCA) to a cardiac chamber or vessel. This can be to the superior caval vein, right atrium, right ventricle, PA, left atrium or to the left ventricle. Embryologically these fistulae represent remnants of the coronary to intramyocardial sinusoidal circulation.

These may be simple direct connections from a coronary to the chamber or vessel or a complex multiple communications. Some communications can be large with significant shunting of blood. They enlarge with time. These fistulae cause *steal* from the myocardium with ischemia, or present with a continuous murmur or as endocarditis. They can often rupture.

Most are asymptomatic and diagnosed incidentally when evaluating a murmur or cardiomegaly noted on CXR. Some large ones can present with CCF in infancy. Others can have exercise intolerance, angina, dyspnea or rarely arrhythmias. They often present with a continuous, patent arterial duct like murmur, which is heard lower down and appears superficial and louder in diastole rather than in systole. ECG has no characteristic findings. CXR may show cardiomegaly. Echocardiography and color Doppler helps display the origin, course and entry points of these fistulae and show multiple fistulae when present.

Treatment can be surgical ligation of these fistulae and increasingly coil embolization or even device closure.

ANEURYSM OF SINUS OF VALSALVA AND RUPTURED SINUS OF VALSALVA

A localized weakness of the wall of a sinus of Valsalva leads to aneurysmal bulging and eventual rupture. These localized aneurysms are usually congenital but may follow infective endocarditis. They occur just above the aortic leaflet hinge point. A majority occur in the right aortic sinus. Up to 50% of these are associated with doubly committed and juxtarterial ventricular septal defects (VSD) or outlet muscular VSDs. Progressive prolapse of the aortic valve leaflets leads to aortic regurgitation (AR), which is usually progressive.

Because the aortic root is a central structure, they can rupture into any cardiac chamber. Usual ruptured sinus of Valsalva (RSOV) is to the right ventricle especially when associated with a VSD. Less commonly the rupture is to the right atrium. Unruptured aneurysms can obstruct the right ventricular outflow, obstruct a coronary, cause heart block due to compression of the conducting system.

Ruptured sinus of Valsalva seldom presents in infancy or early childhood. RSOV to the right ventricle or atrium produces a left to right shunt of varying magnitude. Endocarditis occurs in 5–10%.

Unruptured aneurysms are diagnosed incidentally during routine echocardiograms or angiography for other conditions. Rupture may cause chest or abdominal pain and symptoms of CCF may develop in larger ruptures. There may be a loud continuous murmur resembling a patent arterial duct, but occurring lower

down. AR murmur and an associated VSD murmur may produce confusing findings.

Electrocardiogram may be normal or show chamber hypertrophy with large ruptures. CXR will show enlargement of the chambers ruptured into. In addition, PA dilatation and pulmonary plethora may be noted. Echocardiography and color Doppler as well as transesophageal echocardiography show the details of the aneurysm, site of rupture, presence and severity of AR. Associated VSD will also be seen as well as the hemodynamic effects. CT angiography and magnetic resonance imaging can add to provide good definition of the lesions. Cardiac catheterization and angiography is seldom required nowadays with excellent resolution using other modalities of imaging.

Treatment is primarily surgical repair. Device closure of the RSOV is done but with a risk of further damaging the aortic valve. At surgery the aortic valve can be repaired for the AR or the VSD closed when present.

IN A NUTSHELL

1. Anomalous left coronary artery from pulmonary artery (ALCAPA) may present with ischemia, CCF, incidental cardiomegaly, or as dilated cardiomyopathy. Left untreated, overall outlook is poor with death due to arrhythmia, CCF, cardiogenic shock in a majority. Cornerstone of treatment is surgery.
2. Coronary artery fistulae (CAF) are distal communications from the coronary artery, to a cardiac chamber or vessel. They enlarge with time. These fistulae cause *steal* from the myocardium with ischemia, or present with a continuous murmur or as endocarditis. They can often rupture. Treatment is surgical ligation.
3. A localized weakness of the wall of a sinus of Valsalva leads to aneurysmal bulging and eventual rupture. Rupture may cause chest or abdominal pain and symptoms of CCF may develop in larger ruptures. Treatment is surgical.

Chapter 40.17

Pulmonary Stenosis

Shreepal Jain, Bharat Dalvi

Congenital pulmonary stenosis (PS) may occur at, above or below the valve. It may occur as isolated lesion or in association with other congenital heart defects (CHDs) in up to 25–30% of all congenital heart diseases (CHDs).

VALVAR PULMONARY STENOSIS

Epidemiology

First described by Morgagni in 1761, valvar PS (V-PS) is one of the common CHDs. Although usually isolated, it may be associated with other CHDs such as atrial septal defect (ASD), ventricular septal defect (VSD), and persistent ductus arteriosus (PDA), tetralogy of Fallot (TOF), transposition of great arteries (TGA), double outlet right ventricle (DORV), etc.

Incidence

Valvar PS constitutes 7% of all CHDs accounting for 80–90% of all lesions with right ventricular outflow tract (RVOT) obstruction. It has higher birth prevalence in Asia as compared to Europe and the USA.

Epidemiology and Etiology

There is no specific sex predilection. In isolated PS, the recurrence risk is reported to be 1.7–3.7%. In syndromic PS, the recurrence risk is higher, depending on the inheritance pattern.

Valvar PS occurs frequently in patients with Noonan syndrome, less frequently in Williams-Beuren syndrome, neurofibromatosis and occasionally with 22q11 deletion syndrome. It has been described in Alagille and congenital Rubella syndrome although peripheral pulmonary arterial stenosis (PPS) is the more usual association.

Embryogenesis

Development of semilunar valves requires the formation of endocardial cushions in the cardiac outflow tract and remodeling of these cushions into valve leaflets. Mechanisms of the valve elongation process involve differential proliferation and apoptosis of cushion mesenchymal cells, as well as tissue-tissue interactions among mesenchymal cells, endocardial cells, and myocardial cells, the latter originating from the secondary heart field (SHF). *Calcineurin/Nfatc1* signaling in SHF is essential for semilunar valve development. The absence of SHF calcineurin causes increased apoptosis of conal cushion mesenchyme, leading to failure or abnormal development of semilunar valves.

Pathology

The most common of the two types is the classical or typical valvar PS characterized by a normal sized valve annulus and a thin, pliant or dome-shaped membrane with three well-defined but incomplete raphae extending from the central narrow opening (Fig. 1). Obstruction is mainly secondary to incomplete opening of the leaflets. There is associated poststenotic dilatation of the main pulmonary artery (MPA) usually extending into the left PA (LPA) that may be secondary to high velocity jet hitting the PA after ejecting through the small valve orifice. The degree of dilatation does not correlate with the severity of obstruction and is often more pronounced in mild cases.

Figure 1 Right ventricular angiogram in lateral view demonstrating a typical doming pulmonary valve with thin leaflets (thin arrow) and narrow jet of flow across it along with poststenotic dilatation of the main pulmonary artery (thick arrow)

Dysplastic pulmonary valve, seen in up to 20% of patients, is characterized by hypoplastic annulus, three distinct thick immobile cusps without any commissural fusion. There is usually no poststenotic dilatation of the MPA. It is commonly seen in patients with Noonan syndrome. Obstruction is mainly due to immobility of the thick leaflets.

Moderate and severe degree of stenosis is associated with right ventricular hypertrophy (RVH). Localized hypertrophy of the infundibular region develops in some producing subvalvar obstruction. Tricuspid valve (TV) annulus is usually normal sized but may enlarge with development of right ventricle (RV) failure. Right atrium (RA) is dilated and hypertrophied in severe cases.

Hemodynamics

Right ventricle myocardium normally receives flow throughout cardiac cycle since aortic pressure always exceeds RV pressure. In longstanding moderate to severe PS, systolic flow to RV is reduced causing subclinical infarction and subendocardial fibrosis.

Although a hypertrophied RV is initially able to maintain normal stroke volume, it eventually dilates and fails. With fall in stroke volume, tissue oxygenation during periods of increased demand is maintained by increased oxygen extraction by peripheral tissues leading to widening of arteriovenous oxygen difference (AVO_2) and peripheral cyanosis. In those with a patent foramen ovale (PFO) or ASD, cardiac output might be maintained via right to left shunt at atrial level at the cost of desaturation.

Critical Pulmonary Stenosis

Neonates with critical PS are characterized by severely hypertrophied RV with hypoplastic cavity, systemic or suprasystemic RV pressures, central cyanosis secondary to right to left atrial shunt across the PFO and duct dependent pulmonary blood flow.

Clinical Features

Symptoms

Majority of children with PS are diagnosed due to incidental detection of a murmur. Those with long standing moderate to severe stenosis present with exertional dyspnea and fatigue. Patients with untreated severe PS have exercise-induced chest

pain, syncope or even sudden cardiac death. Occasionally, they present with generalized anasarca secondary to RV dysfunction. Neonates with critical PS present with severe cyanosis at birth and may develop severe hypoxia and acidosis with PDA closure.

Signs

Growth and development is usually normal except in those with Noonan or Rubella syndrome. Typical facies may be seen in Williams, Noonan and Alagille syndromes. Central or peripheral cyanosis may be detected for reasons described earlier. Peripheral pulse is usually normal in mild-moderate cases and may be reduced in severe PS with RV failure. The *a* wave in jugular venous pressure (JVP) tends to be progressively larger with increasing severity of PS due to stronger atrial contraction. With development of tricuspid regurgitation and RV failure, the *v* wave becomes more prominent with a brisk *y* descent.

Palpation may reveal RV systolic impulse along the left parasternal border. In moderate and severe PS, there may be a palpable thrill in the second left intercostal space (LICS), radiating upwards and towards the left.

On auscultation, *S*₁ is usually normal. This is immediately followed by a high-pitched, sharp pulmonary ejection click (PEC), heard maximal in the second left intercostal space (LICS). The click is not heard in those with dysplastic valve. *S*₁-PEC interval decreases with increasing severity of PS and PEC may be difficult to separate from *S*₁ in severe PS. Intensity of PEC decreases with deep inspiration and increases on expiration. *S*₂ in PS is usually split, with the degree of splitting being proportional to the severity of stenosis. The split may become fixed in severe stenosis as a result of a fixed stroke volume. Pulmonary component (*P*₂) tends to become softer with increasing severity, making split difficult to appreciate. A fourth heart sound (*S*₄) is often heard at the lower left sternal border in patients with severe PS.

Murmur is ejection systolic type heard maximally in second LICS and radiating upwards and to the left. In mild PS, the murmur peaks in mid-systole and ending at or before the aortic component of second heart sound (*A*₂). With increasing severity, the peak tends to occur later in systole and even extending beyond *A*₂.

Neonates with critical stenosis tend to have softer systolic murmur as a result of reduced right ventricular output across the pulmonary valve. *P*₂ is usually not audible in such cases.

Investigations

Electrocardiogram

In mild PS, rightward QRS axis or an upright T wave in V1 may be the only finding in an otherwise normal looking electrocardiogram (ECG). Right axis deviation (RAD), R : S ratio in lead V1 more than 4 : 1 and R more than 20 mm are common findings in moderate PS. With severe stenosis, further RAD, monophasic R wave in lead V1 and deep S waves in the left precordial leads, with an R : S ratio less than 1 in V6, can be seen. Inverted T waves can be seen in II, III, aVF and right precordial leads. T wave inversion in the precordial leads beyond V3 is suggestive of suprasystemic RV pressure. In patients between 2 years and 20 years, a rough estimate of the RV systolic pressure can be obtained if there is a pure R wave in lead V1 or V_{4R} by multiplying its height (in millimeters) by 5.

In those with critical PS or severe PS with hypoplastic RV cavity, the QRS axis tends to more leftward than expected (+30° to +70°) with evidence of left ventricular hypertrophy. These neonates or infants have adult progression of R-wave in precordial leads. Infants with Congenital Rubella and Noonan syndrome may have left axis deviation of the QRS complex.

Radiology

Cardiac size is usually normal except in cases with tricuspid regurgitation (TR) and RV failure or in neonates with critical PS (**Fig. 2**). Most notable finding is a prominent main PA segment secondary to poststenotic dilatation. Pulmonary vascularity is normal unless reduced by development of RV failure or large right to left atrial level shunt in critical PS.

Echocardiogram

A two-dimensional echocardiogram (2DE) is now the investigative modality of choice for confirming the diagnosis of PS. It can help in differentiating a typical doming PS valve with thin leaflets from a thick, dysplastic valve. In addition, secondary changes like poststenotic PA dilatation, RVH, infundibular hypertrophy and tricuspid valve (TV) anatomy and function can be assessed. Color Doppler echocardiography adds to the information by exactly locating the origin of flow turbulence, whether valvar, subvalvar or supravalar. Other information like flow across any atrial level shunt can also be identified. Severity of stenosis can be estimated by Doppler interrogation of the jet across the pulmonary valve using the simplified Bernoulli equation.

Cardiac Catheterization and Angiography

With the advent of echocardiography, catheterization is now mainly reserved for interventional purpose. Important hemodynamic information that can be obtained includes RV systolic pressure, which can be compared with the systemic systolic pressure and the gradient across the pulmonary valve. In addition, presence of infundibular component can be detected with the help of an end-hole catheter. PA pressure is usually normal or may be low in severe PS with RV dysfunction. Elevated RV end diastolic pressure is suggestive of severe RV hypertrophy with diastolic dysfunction. RA pressure is usually normal unless there is associated RV failure or significant tricuspid regurgitation.

RV angiogram provides information about the valve morphology, annulus size, presence or absence of poststenotic dilatation of PA, infundibular component (fixed versus dynamic), RV cavity size and function, and TV function.

Differential Diagnosis

Conditions mimicking mild PS include innocent or functional murmurs, ASD, idiopathic dilatation of PA, mitral valve prolapse,

Figure 2 Chest radiograph in a newborn with critical pulmonary stenosis depicting cardiomegaly with dilated right atrium. Radiographic appearance may be similar to that seen in a neonate with Ebstein anomaly

and mild aortic stenosis. Moderate and severe PS need to be differentiated from small to moderate sized VSD and moderate to severe AS. Neonatal critical PS needs to be differentiated from Ebstein anomaly with functional pulmonary atresia and pulmonary atresia with intact ventricular septum.

Management

Balloon Pulmonary Valvuloplasty

Balloon pulmonary valvuloplasty (BPV) is the procedure of choice for moderate and severe PS with typical doming pulmonary valve as well as the initial therapy for dysplastic valve. With advancement in catheter and balloon hardware, it is now possible to treat even newborns with critical PS with good results. Balloon diameter is chosen as 1.2–1.4 times the angiographically measured pulmonary annulus size. Mechanism of obstruction relief involves commissural splitting after balloon inflation (**Figs 3A and B**). As a result, pulmonary regurgitation (PR) is a natural consequence of the procedure and an indirect indicator of adequate dilatation. Pullback pressure recording with an end-hole catheter is done after the dilatation to assess the amount of relief. Occasionally some residual gradient may be noted across the infundibular region. This dynamic gradient resolves once the hypertrophied infundibular muscle regresses. Rarely, β -blocker treatment is necessary to relieve this dynamic obstruction after BPV.

As per the American Heart Association scientific statement, Class I indications for BPV include critical PS and valvar PS with catheter measured or echocardiographically measured peak instantaneous gradient of more than or equal to 40 mm Hg or clinically significant valvar PS with evidence of RV dysfunction.

At midterm follow-up (< 2 years), restenosis is observed in 8–10% of patients. In the absence of severe annular hypoplasia and valvar dysplasia, this can be treated with a repeat BPV using a larger balloon with good success rates. In the long-term follow-up, the freedom of reintervention is reported as 88% and 84% at 5 and 10 years, respectively. Reported incidence of adequate obstruction relief in those with dysplastic valve ranges from 35% to 65%.

In newborns with critical PS, immediate effective gradient reduction is achieved in more than 90% patients. However, 5–10% patients are unable to maintain adequate forward flow across the pulmonary valve. Usually these babies can be maintained on

prostaglandin E1 infusion for providing adequate pulmonary blood flow (PBF) before gradually weaning it. However, a stable source of PBF in the form of surgically created aortopulmonary shunt or a transcatheter PDA stenting may be required if they are unable to be weaned even after 2–3 weeks. Another 10% may require repeat BPV within months of the initial procedure.

Incidence of moderate PR after BPV ranges from 5% to 24%. Incidence of moderate to severe PR appears to increase over period of time. Moderate or severe pulmonary insufficiency developed in 74% of patients who underwent the procedure as neonates, in contrast to 44% of all other patients. Longstanding moderate to severe PR has deleterious effects on RV function and exercise tolerance as well as increased incidence of arrhythmias. Such patients may need a pulmonary valve replacement (PVR) to minimize these risks.

In experienced hands, risk of procedure related death (0.24%) or major complications (0.35%) are very low. Complications, including transient bradycardia and hypotension during balloon inflation, transient or permanent right bundle branch block or atrioventricular block, balloon rupture, tricuspid valve chordae/papillary muscle rupture, and tears in the pulmonary artery have been reported, but rarely.

Surgical Valvotomy

Surgery is now reserved for only those with dysplastic valves with inadequate relief after BPV or those with multiple levels of obstruction. Adequate relief of obstruction often necessitates complete removal of the valve annulus and leaflets and insertion of transannular patch. As a result, moderate to severe PR is common in such patients. Restenosis rate is very low with up to 96% remaining free of reintervention at 10 years follow-up.

Outcome

The natural history of patients with mild PS is usually benign. In the Second Natural History study, patients with catheter measured gradient less than or equal to 25 mm Hg had normal survival and no progression of their stenosis in 25 years of follow-up; patients with a gradient between 25 mm Hg and 49 mm Hg had a 20% chance of ever needing an intervention; and the majority of patients with a gradient more than or equal to 50 mm Hg experienced progressive stenosis and required intervention.

Figures 3A and B (A) Balloon dilatation of the pulmonary valve being performed with the balloon positioned across the annulus suggested by the waist (arrow); (B) Infundibular spasm (arrows) noted after the balloon dilatation, which may be responsible for transient persistence of gradient across the right ventricle to pulmonary artery

Infective endocarditis (IE) prophylaxis is not recommended for patients with PS. Patients with mild PS can live normal lives, without any exercise restriction. Those with moderate PS and normal biventricular function can participate in moderate levels of exercise and avoid competitive and static sports. In patients with severe PS, the stenosis must be resolved before they can resume unrestricted physical activity. While awaiting intervention, they should be restricted to low intensity sports.

SUBVALVAR PULMONARY STENOSIS

This may be secondary to either infundibular narrowing or due to anomalous muscle bundle in the RV cavity (double chambered right ventricle [DCRV]).

Primary infundibular stenosis Being rare, it accounts for about 5% of all cases of right ventricular outflow tract (RVOT) obstruction. It may be due to either an obstructive fibrous band at the junction of the main right ventricular cavity and the proximal infundibulum (resembling DCRV) or tunnel like narrowing of the infundibulum due to fibromuscular thickening of its wall. Hemodynamic and clinical features are similar to DCRV.

Double-chambered right ventricle Presence of anomalous muscle bundles across the mid-RV cavity divides it into a proximal high-pressure chamber and a distal low-pressure infundibular chamber. Embryologically, these muscle bundles could represent an arrested incorporation of the primitive bulbus cordis into the right ventricular body. A VSD is frequently present.

Clinical Features

Symptoms are similar to those with isolated valvar PS and progress with age. Symptoms of VSD may dominate if it is large. A loud pansystolic murmur usually with a thrill is audible located relatively low as compared to valvar PS (usually fourth left intercostal space). Click is absent and the pulmonary component of S_2 may not be as soft or delayed as in valvar PS. ECG may show evidence of RVH. An inverted T wave in lead V_{3R} may be the only finding in up to 40% patients with DCRV.

Diagnosis

Diagnosis as well as severity can be readily confirmed on echocardiography. Ventricular septum can also be evaluated for presence of VSD. Cardiac catheterization can reveal the presence of gradient from the high-pressure proximal inflow portion to the distal low-pressure infundibular portion. Magnetic resonance imaging (MRI) can be helpful in diagnosing as well as quantifying the severity in older children and adults with poor echocardiographic windows.

Management

It includes surgical excision of the anomalous muscle bundles in moderate to severe cases along with closure of any associated VSD. Long-term results after surgery are excellent.

PERIPHERAL PULMONARY STENOSIS

Stenosis of the pulmonary arteries, isolated or in association with other cardiac defects, accounts for 2–3% of all CHD. The stenosis may be single, involving the main pulmonary artery or either of its branches, or multiple, involving both the main and several smaller peripheral pulmonary artery branches.

Most common associations include valvar pulmonary stenosis, VSD, and tetralogy of Fallot. Several congenital syndromes are commonly associated with PPS namely congenital rubella, Williams, Noonan, Alagille, cutis laxa, Ehlers-Danlos syndrome, and Silver-Russell syndrome.

Embryogenesis

The proximal branch pulmonary arteries are embryological derivatives of the sixth branchial arches on either side. The peripheral portions of the pulmonary artery branches derive from the post-branchial pulmonary vascular plexus lying in close relationship to the growing lung buds. Embryologic basis of PPS tends to differ with the underlying insult. Teratogenic agents like rubella virus appear to interfere with normal formation of elastin tissues. Abnormal elastin production seems to be defect in Williams syndrome. Ductal closure may be etiology for proximal PA stenosis in cyanotic CHD.

Physiology

In cases with multiple bilateral stenoses, the RV and proximal PA pressure are elevated in proportion to the severity of stenosis. Resting RV pressure tends to remain normal in unilateral stenosis without vascular disease in the contralateral lung as a result of accommodation of the cardiac output by the normal contralateral pulmonary bed.

Clinical Features

Majority with mild to moderate stenosis tend to be asymptomatic. Those with severe multiple or bilateral stenosis may present with dyspnea on exertion, easy fatigability or signs of right heart failure. S_1 is normal and click is usually absent unless associated with valvar PS. S_2 is normally split with loud P_2 in cases with multiple peripheral stenosis. Characteristic murmur is systolic in nature beginning sometime after S_1 , heard well in pulmonary area and transmitted widely to axilla and back. Occasionally a continuous murmur may be heard signifying severe stenosis with presence of gradient even during diastole.

Investigations

Electrocardiogram

Typical findings include evidence of right atrial enlargement and RVH. Patients with Noonan and congenital rubella syndrome tend to have a higher incidence of left axis deviation.

Chest Radiograph

Right atrial and ventricular enlargement may be noted in those with severe PPS. Occasionally poststenotic dilatation of peripheral arteries may produce small vascular shadows in the perihilar lung fields.

Echocardiography

Elevated right ventricular pressure can be detected by Doppler interrogation of the tricuspid regurgitation jet. Proximal PA stenosis can be readily detected on color Doppler evaluation. However, distal PAs are difficult to assess by this modality.

Others

Alternative imaging such as computerized tomography (CT) and MRI are now considered the noninvasive modalities of choice for PPS. MRI and nuclear lung perfusion scans can quantify the proportion of blood flow to each lung segments which can aid in decision making regarding need and timing of intervention. Cardiac catheterization is now usually reserved for interventions.

Differential Diagnosis

These are similar to those with valvar PS. Presence of cyanosis should suggest diagnosis like tetralogy of Fallot or other complex cyanotic conditions.

Management

- **Surgery** Main PA and the proximal branch PA can be addressed surgically by enlarging the stenosed segment with autologous pericardial patch. Distal PAs are difficult to access surgically and are best treated by transcatheter measures.
- **Balloon angioplasty** Balloon dilatation affords relief by producing tear in the intimal and medial layer of the pulmonary vascular wall. Success rates have significantly improved with the availability of high-pressure balloons and cutting balloons. Initial success rate for isolated PPS is reported around 50% with a high restenosis rate of 35%. Resistant vessels may be dilated with cutting balloons with microsurgical blades mounted longitudinally on the balloon. Although initial success rate is reported as high as 92%, further long-term follow-up details are not available. Complications of angioplasty are seen in up to 10% cases and include pseudoaneurysm formation, hemoptysis, ipsilateral pulmonary edema, dissection, and thrombosis related to vascular access.
- **Intravascular stents** Excellent initial and mid-term follow-up results are reported with balloon angioplasty and placement of stainless steel balloon mounted stents with greatly enhanced success rate of 100% and increase in vessel diameter and more than 75% reduction in the pressure gradient. Stent redilatation may be needed especially in infants and young children. Complication (rate: 0–40%) includes stent migration, embolization, stent thrombosis, pulmonary edema and hemorrhage.

Infective endocarditis prophylaxis is not indicated for isolated PPS with intact ventricular septum. For those with surgically placed patch or catheter delivered stents, IE prophylaxis is indicated for the initial 6 months after procedure.

Outcome

Children with mild to moderate stenosis tend to remain stable. Patients with Williams, Rubella or Noonan syndrome may in fact have reduction of severity with age. Severe stenosis is progressive and if untreated, may lead to right ventricular failure or pulmonary hemorrhage from rupture of poststenotic aneurysmal artery.

IN A NUTSHELL

1. Pulmonary stenosis can be valvar, subvalvar or peripheral (involving the pulmonary artery).
2. Valvar PS constitutes 7% of all CHDs accounting for 80–90% of all lesions with right ventricular outflow tract (RVOT) obstruction.
3. Moderate and severe degree of stenosis is associated with right ventricular hypertrophy (RVH).
4. Majority of children with PS are diagnosed due to incidental detection of a murmur. Those with long standing moderate to severe stenosis present with exertional dyspnea and fatigue. Neonates with critical PS present with severe cyanosis at birth and may develop severe hypoxia and acidosis with PDA closure.
5. Balloon pulmonary valvuloplasty is the treatment of choice for moderate and severe PS.

Chapter 40.18

Coarctation of Aorta

Kshitij Sheth, Bharat Dalvi

Coarctation term derived from Latin *coartatio*, means crowding together. Aortic coarctation, therefore, indicates a narrowing at some point along the course of the aorta. Coarctation of aorta (CoA) varies considerably in its anatomy, physiology, clinical presentation, treatment options and outcomes.

EPIDEMIOLOGY

Aortic coarctation accounts for 7% of liveborn children with congenitally malformed hearts, with a higher incidence in stillborn infants. The overall incidence is 1 in 12,000, with a slight male preponderance with male : female ratio of 1.74 : 1.

ETIOLOGY

The exact etiology of coarctation is not known, but it is assumed to be multifactorial. It includes genetic predisposition, as it is known to recur in families. There is a suspicion of environmental influence with incidence of coarctation peaking in the late fall and winter. The genetic basis of occurrence of CoA has long been recognized, as it is an associated finding in 35% of Turner's syndrome. If one of the parents has CoA, the risk of recurrence in the offspring is about 2–4% and with a previous affected sibling with coarctation, the risk in next sibling is about 2%. There are various theories for development of coarctation:

Ductal tissue theory Normally the junction between the ductal tissue and elastic aorta is clearly defined and the ductal tissue into aortic wall does not extend beyond 30% of circumference (**Fig. 1**). However, in CoA, there is extensive infiltration of ductal tissue into aortic lumen, causing constriction of lumen resulting in obstruction.

Hemodynamic theory It proposes that coarctation develops because of hemodynamic disturbances that reduce the volume

of blood flow through the fetal aortic arch. In the normal fetus the aortic isthmus receives only 10% of the combined ventricular output explaining the observed lesser diameter of the normal isthmus (70–80% of that of neonatal ascending aorta). Intracardiac shunt lesions that diminish the volume of left ventricular (LV) outflow is said to promote development of coarctation in the fetus by reducing volume of blood flow through the aortic isthmus.

Neural crest cells Migration of neural crest cells towards the arch has been shown to play a role in development of interruption of the aortic arch. The same analogy can be applied to development of coarctation.

Fetal lymphatic obstruction This theory has been proposed for development of coarctation in patients with Turner's syndrome. It is suggested that fetal lymphatic obstruction, which may cause the webbed neck in Turner's syndrome, also leads to distended thoracic ducts that compress the fetal ascending aorta and thereby promote the development of coarctation.

PATHOPHYSIOLOGY

The terms used in the past such as *preductal* and *postductal* as well as *infantile* or *adult-type* CoA are misleading. CoA is almost always in a juxtaductal position. However, there are variations in morphology of coarctation with varying degree of obstruction (**Fig. 2**).

- **Shelf lesion** Typical coarctation lesion wherein there is an anterior and posterior shelf.
- **Waist lesion** It is a severe form of shelf lesion where the lumen constricts severely due to anterior and posterior shelf to form a tight waist with proximal tapering.
- **Tubular hypoplasia** Tubular hypoplasia is present when there is a uniform narrowing of part of the arch.
- **Arch atresia** A part of the arch is atretic with only fibrous cord connecting the atretic segment to distal aorta.
- **Interruption** This is an extreme form of arch obstruction in which a segment of the arch is absent. Depending upon the site of interruption, it is classified as Type A, B and C.

Pseudocoarctation refers to an anomaly characterized by buckling and kinking of aorta in vicinity of ligamentum arteriosum, resulting in elongation, tortuosity and distention of distal aortic arch and proximal descending aorta.

Simple versus Complex Coarctation

Simple coarctation Coarctation of aorta with or without patent ductus arteriosus (PDA).

Complex coarctation Coarctation of aorta associated with other intracardiac lesions such as bicuspid aortic valve (70–80%), ventricular septal defect (VSD) (35–40%), atrioventricular septal defect (AVSD) (10%), transposition of great arteries (TGA) (8%), double-outlet right ventricle (DORV) (6%). Other associations include hypoplastic left heart syndrome (HLHS), atrial septal defect (ASD), tricuspid atresia and pulmonary atresia with VSD.

Coarctation can also be a part of *Shone's complex* which includes left-sided obstructive lesions like supramitral membrane, parachute mitral valve, subaortic stenosis (membranous or muscular) and coarctation of the aorta. It can be extended to include other left side lesions like bicuspid aortic valve with stenosis and supra-ventricular stenosis. Extracardiac associated lesions include Berry aneurysm of circle of Willis (3–5%) and aberrant brachiocephalic artery anatomy (4–5%).

Figure 1 Extension of ductal tissue into the aorta: Normal: Less than 30% of circumference; CoA: Extensive infiltration around most of the aortic circumference

HEMODYNAMICS

Symptomatic newborn with CoA During fetal life (and at birth), the descending aorta is supplied mostly by right-to-left ductal flow

Figure 2 Variations in morphology of coarctation with varying degree of obstruction

and by a significantly reduced amount of antegrade aortic flow through the aortic isthmus. Other associated cardiac defects such as aortic arch hypoplasia, abnormal aortic valve, VSD, and mitral valve anomalies are often present. All these cardiac defects tend to decrease the antegrade aortic blood flow in utero. With ductal closure, a reduced antegrade aortic flow to the descending aorta produces symptoms early in life. Good collateral circulation has not developed in these neonates. Occasionally, infants without associated defects may become symptomatic because of LV failure, which results from a sudden pressure overload in early postnatal life.

Asymptomatic infants and children with CoA During fetal life, the descending aorta is supplied by both a normal amount of antegrade aortic flow through the aortic isthmus and normal ductal flow because associated cardiac defects are rare in these children. Good collateral circulation gradually develops between the proximal aorta and the distal aorta during fetal life.

Major *collateral circulations* between the aortic segments proximal and distal to the coarctation comprise of the internal mammary artery; arteries arising from the subclavian artery by way of the intercostal arteries and the anterior spinal artery.

CLINICAL FEATURES

Coarctation of aorta has bimodal presentation. Neonates and infants can present with acute LV failure or with cardiovascular

collapse, renal failure and acidosis. Children and adolescents may present with an incidental murmur, or as hypertension or any of the complications of hypertension.

Infancy Patients usually present with catastrophic features once the ductus closes. Most of the babies are associated with other intracardiac lesions. An infant with severe coarctation presents with acute heart failure, shock, and acidosis, which often develop suddenly at approximately 8–10 days of life. Multiorgan failure, particularly renal failure and/or necrotizing enterocolitis and death occur rapidly unless definitive medical and surgical interventions are provided immediately.

Children and adolescents Coarctation of the aorta often presents later in childhood as systolic hypertension or as a heart murmur. Some of them may present as complication related to hypertension, such as acute LV failure or stroke. Delayed diagnosis beyond infancy is common because the physical findings may be subtle and most of these children are asymptomatic. On careful investigation, some children will report lower-extremity claudication with exercise or frequent headaches.

Physical Examination

The appearance of a child with coarctation will vary depending on the mode of presentation. In an infant with congestive heart failure, one encounters a pale, irritable child in respiratory distress. Signs of congestive cardiac failure like tachycardia, dyspnea, diaphoresis

and hepatomegaly. In contrast, the appearance of an older child with coarctation may be entirely benign.

The hallmark physical findings in coarctation consist of discrepant arterial pulses and blood pressures in the upper and lower extremities. Arterial pulses below the coarctation are diminished in amplitude and delayed in timing compared with the proximal pulses (radiofemoral delay). Systolic blood pressure is elevated proximal to the coarctation, and a systolic pressure gradient is present between the arm and leg (difference more than 20 mm Hg).

In a sick infant the S_2 is single and loud; a loud S_3 gallop is usually present. No heart murmur is present in 50% of sick infants. Occasionally an ejection systolic murmur may be audible over the precordium arising from bicommissural aortic valve.

In an older child, a systolic thrill may be present in the suprasternal notch. The S_2 splits normally, and the A_2 is accentuated. An ejection click is frequently audible at the apex and/or at the base, which originates in the associated bicuspid aortic valve or from systemic hypertension. An ejection systolic murmur grade 2 to 4/6 is heard at the upper right sternal border and middle or lower left sternal border. A well-localized systolic murmur is also audible in the left interscapular area in the back.

Investigations

Chest X-ray The heart size may be normal or slightly enlarged if LV failure sets in. Dilation of the ascending aorta may be seen. An E-shaped indentation on the barium-filled esophagus or a 3-sign on overpenetrated films suggests CoA. Rib notching (**Figs 3A and B**) between the fourth and eighth ribs may be seen in older children but rarely in children younger than 5 years.

Electrocardiogram (ECG) Leftward QRS axis and left ventricular hypertrophy (LVH) are commonly found (**Fig. 4**). The ECG appears normal in 20% of patients.

Echocardiogram Two-dimensional echocardiogram (2D-ECHO) helps in establishing the diagnosis and gives information regarding site and extent of coarctation, presence of *posterior shelf* at site of coarctation, degree of isthmic and transverse arch hypoplasia, presence of LV hypertrophy and status of LV function.

Doppler evaluation Helps in quantifying the severity of CoA by assessing the gradients across the CoA segment. Poor pulsation of the abdominal aorta with continuous flow on Doppler is an indirect evidence of severe coarctation. It shows the gradient across the coarctation with continuous flow across the segment. This helps to assess the severity of coarctation.

Magnetic resonance imaging (MRI)/Computed tomography (CT) scan Echocardiography is a superior modality for the diagnosis of coronary heart disease (CHD) in infants and young children, and CT scan/MRI has a limited role in smaller children because of the need for sedation or anesthesia, transportation, use of contrast, radiation exposure and higher cost. However, CoA is an exception. CT and MRI offer better anatomical delineation of CoA.

Cardiac catheterization and angiography In most cases, sufficient information can be obtained from clinical and noninvasive examination to decide on an appropriate plan for management. Occasionally one may have to resort to CT/MRI. Cardiac catheterization is of limited value in the diagnosis of CoA. Its role is mainly for therapeutic interventions in the form of balloon angioplasty, with or without stenting.

MANAGEMENT

Coarctation in a Newborn or Infant

Stabilization In symptomatic neonates, prostaglandin E1 (PGE1) infusion (0.05–0.1 mcg/kg/min) should be started to reopen the ductus arteriosus and establish flow to the descending aorta and the kidneys. Intensive anticongestive measures with inotropic agents (e.g., dopamine, dobutamine), diuretics and oxygen should be started.

Balloon angioplasty This can be a useful bridging procedure for sick neonates in whom standard surgical management carries a high risk. However, in well-compensated newborns and infants, balloon angioplasty is associated with a higher rate of recoarctation than surgical repair, and the rate of complications (including femoral artery injury) is also high during infancy.

Surgical intervention If CHF or circulatory shock develops early in life, surgery should be performed on an urgent basis (**Fig. 5**). A short period of medical treatment, as described earlier, improves the patient's condition before surgery.

Recurrence rate	< 10%	10–30%	Around 40%
			

Figure 5 Types of surgeries in coarctation of aorta

Coarctation in an Older Child

Medical management Children with mild CoA should be watched closely for hypertension in the arm. Drugs used for management of hypertension include beta-blockers, angiotensin converting enzyme inhibitors (ACEIs) and, angiotensin receptor blockers (ARBs). In children, on treatment with ACEI and ARBs, close monitoring of renal function is necessary. Good dental hygiene and precautions against subacute bacterial endocarditis (SBE) are important.

Balloon angioplasty For native unoperated coarctation, balloon angioplasty is now considered by most centers as primary treatment of coarctation (**Figs 6A to C**). It is also the procedure of choice for recoarctation. However, some centers still prefer a surgical approach. The most common acute complication of balloon angioplasty has been femoral artery injury and thrombosis, especially in small children. There is a possibility of aortic aneurysm formation with serious late complications. Also, hemodynamic results with deployment of stent are more predictable.

Balloon-expandable stent (covered/uncovered) Balloon expandable stent implanted concurrently with balloon angioplasty is now procedure of choice in western world in children older than 8–10 years old. This helps to reduce the chances of dissection and pseudoaneurysm formation.

Surgical repair It includes end-to-end anastomosis, subclavian flap, patch aortoplasty and aortic jump graft. Elective correction is done between 2 years and 4 years in asymptomatic child with no hypertension and normal LV function. Earlier intervention is recommended in those with symptoms in form of shortness of breath, giddiness, black outs or development of hypertension or reduction of aortic diameter less than 50% or cardiomegaly on X-ray or LV dysfunction.

OUTCOMES

Surgical intervention in infants has mortality less than 2%. Complications include spinal cord ischemia, rebound hypertension and recoarctation (5%). Catheter intervention carries risk of mortality less than 3%.

Other complications include dissection, pseudoaneurysm, limb ischemia, recoarctation (10% in infancy, less than 5% in older children).

The prognosis for a normal life following successful repair of coarctation in childhood is excellent. Normal growth and development are to be expected, and no significant restrictions should be placed on physical activity. The long-term prognosis after coarctation repair may be profoundly affected by associated intracardiac lesions such as aortic or mitral valve disease. Patients who required repair of intracardiac defects in infancy, such as repair

Figures 6A to C Balloon dilation of coarctation of aorta: (A) Severe coarctation of aorta; (B) Balloon dilation; (C) Postdilation

of a VSD, may have long-term sequelae that include residual VSDs, postoperative heart block and progressive LV outflow obstruction. Such patients require lifelong cardiology follow-up, and many will require additional transcatheter or surgical interventions later in life.

IN A NUTSHELL

1. Coarctation of aorta has bimodal presentation. Neonates and infants can present with acute LV failure or with cardiovascular collapse, renal failure and acidosis. Children and adolescents may present with an incidental murmur, or as hypertension or any of the complications of hypertension.
2. The hallmark physical findings in coarctation consist of discrepant arterial pulses and blood pressures in the upper and lower extremities. Arterial pulses below the coarctation are diminished in amplitude and delayed in timing compared with the proximal pulses (radiofemoral delay). Systolic blood pressure is elevated proximal to the coarctation, and a systolic pressure gradient is present between the arm and leg (difference more than 20 mm Hg).
3. Balloon angioplasty is now considered as primary treatment of coarctation.

Chapter 40.19

Aortic Stenosis

Smita Mishra

A normal aortic valve is a trileaflet structure, located at left ventriculoarterial junction. The term *aortic stenosis* (AS) is generally used to refer to any of the fixed left ventricular outflow tract (LVOT) obstructive lesions found at the level of aortic valve, above or below. At times obstruction of LVOT may be present at more than one level. The valvar aortic stenosis (VAS) is the most common, while subaortic and supravalvar AS are infrequent and they rarely manifest in early infancy. The supravalvar stenosis is usually suspected when child has certain dysmorphic facial features; whereas patients with subaortic stenosis may often have an associated operated or unoperated congenital heart disease.

ETIOLOGY

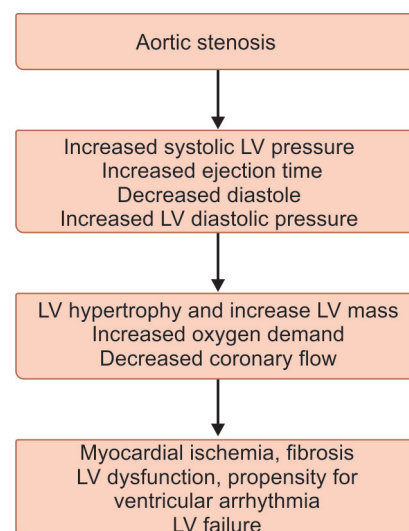

Valvar AS accounts for 70–91% of cases of AS. The majority of valvar AS in pediatric age group can be attributed to bicuspid valve. Few of them may present as critical AS in early neonatal period or later in infancy. Many of them may remain asymptomatic till the 4–5th decades of life. Unicuspid valves commonly present early as the critical AS and are poor candidate for ballooning procedures. The early stenosis of the tricuspid aortic valve can be due to the annular hypoplasia or myxoid dysplasia of valve leaflets. These anomalies are shown in **Figures 1A to E**.

The overall incidence of AS is 0.03–0.34 per 1,000 livebirths and constitutes about 7% of all congenital cardiac malformations. The prevalence of congenital bicuspid valve is 1.3%. Of that 2% patients will experience significant AS or regurgitation by adolescence.

PATHOPHYSIOLOGY

The AS increases work load of myocardium due to increased systolic pressure of LV and prolonged ejection time (**Flow chart 1**). Diastole-dependent coronary flow gets compromised. Moreover, the secondary LVH may be inappropriate and maladaptive and a substrate for malignant ventricular arrhythmias and heart failure. It is caused by the cusp deformities with or without narrowing of the *annulus*. It may manifest early infancy or later as the progressive obstruction of the inherently abnormal valve. The valvar AS has been found in isolation or may be an important component of familial syndromic states. *NOTCH 1* gene may be an etiological factor for familial occurrence of AS. It may be associated with genetic syndromes like Turner syndrome and Jacobsen syndrome.

Flow chart 1 Pathophysiology of aortic stenosis

Other Causes of Valvar AS

Usually mitral valve (MV) gets involved in rheumatic process and AS with or without aortic regurgitation (AR) is found additionally in one-fourth to one-fifth cases with rheumatic heart disease (RHD). Isolated aortic valve involvement is present in less than 10% cases. These patients are usually unsuitable for ballooning procedure. The systemic inflammatory diseases and metabolic disorders may also cause some degree of AS (**Table 1**).

VALVAR AORTIC STENOSIS

Table 2 provides differentiating features of various types of AS.

Aortic Stenosis Beyond Infancy

Normal growth and development is the rule in children presenting later in life. The common symptoms of easy fatigability, exertional dyspnea, angina pectoris, and syncope are present only in

Table 1 Causes of valvar aortic stenosis

Congenital	Abnormal number of cusps: Bicuspid, unicuspid, quadricuspid and other

Sex	Male dominance		
Symptoms	CHF in neonates and infants, older kids effort intolerance, angina, syncope	Effort intolerance, angina, syncope	Effort intolerance, angina, syncope
Arterial pulse	Slow rise delayed peak narrow pulse pressure—pulsus parvus and tardus	Asymmetrical, right arm has high systolic pressure	Slow rise delayed peak, HOCM: brisk rise double peaked
Thrill location	Right and left upper sternal border radiating to carotids	Right upper sternal border	Right and left upper sternal border
Cardiac impulse	Heaving, localized, with presystolic motion, LV type, neonates may present with RV dominance	Heaving, localized	Heaving and localized
S ₁	Normal	Normal	Normal
S ₂	Normal or narrow or reverse split		
A ₂	Delayed		
P ₂	Normal		
LV S ₃	Frequently present		If present s/o severe AS with LV dysfunction
S ₄	LV-S ₄ may be present		
Ejection click	Constant ejection click right upper, left lower sternal border	No	
Murmur	ESM, crescendo-decrescendo, in right upper and left upper and lower sternal border and apex		ESM, crescendo-decrescendo, in RUSB, LLSB and apex
Murmur on standing	Decreased	-	Increased
Murmur on squatting	Increased		Decreased
Murmur on Amyl nitrite	Increased intensity		Increased intensity
ECG	LAD/LVH, Neonates/infants: RVH		LAD/LVH/abnormal Q wave may represent septal hypertrophy in a subset of patient
X-ray chest	Mild to moderate cardiomegaly, LVH, ascending Ao is dilated	Mild to moderate cardiomegaly, LVH, ascending Ao not dilated	
Associations	Turner syndrome, Jacobsen syndrome, <i>Notch1</i> gene	William syndrome	Other CHDs

moderate to severe stenosis. Easy fatigability is common in severe stenosis (15% in mild and 31% in severe AS), whereas angina or syncope are reported in less than 10% of patients even when peak-to-peak pressure gradients are greater than 80 mm Hg. Nevertheless, patients presenting with angina or syncope have grave prognosis.

Appearance of clinical signs other than murmur usually suggests moderate to severe stenosis. Arterial pulse in post neonatal infants is low amplitude and slow rising type (pulsus parvus et tardus) best appreciated in the carotid pulse. Beyond infancy, children with severe AS have forceful and sustained (heaving) LV apical impulse. Often, a thrill is felt in suprasternal notch (85% cases) and in precordium. A presystolic tap indicates forceful atrial contraction in response to elevated left ventricular end diastolic pressure (LVEDP). Auscultatory findings are described below:

Heart Sound

S₁ is normal. The splitting of the S₂ may be normal, narrow, absent or paradoxical due to delayed A₂, according to the severity of stenosis. Audible S₄, if present suggests severe aortic stenosis.

Systolic Constant Ejection Click

A hallmark of bicuspid AV remains same during the respiratory cycle in its timing and intensity even if the valve is functionally normal. Systolic ejection clicks occur in early systole and may result from either the abrupt opening of the semilunar valves or the rapid distention of the proximal aorta at the onset of ejection and they may disappear in presence of calcific AV. The aortic ejection click must be distinguished from tricuspid component (T1) of S₁ and S₄ and pulmonary ejection clicks.

Ejection Systolic Murmur

The systolic (diamond-shaped on phonocardiographic recording) crescendo-decrescendo ejection murmur follows the click, is heard over the right upper sternal border (primary aortic area), lower sternal border and/or apex (**Fig. 2**). It radiates into the neck over the carotid arteries bilaterally. Increasing severity of stenosis is accompanied by a louder, harsher, and later-peaking ESM.

Presence of hyperdynamic systolic carotid thrill, pulsus bisferiens and early diastolic murmur suggests associated AR.

Figure 2 Phonocardiogram: Murmur of aortic stenosis

Aortic Stenosis in Neonates

Any neonate presenting with circulatory shock and low volume pulses must be immediately investigated for critical left sided obstructive cardiac lesions. Neonates with critical AS are often moribund and have congestive heart failure as well as circulatory shock. They often get wrongly interpreted to have right heart failure due to presence of epigastric pulsations and hepatomegaly. Critical AS is categorized as a ductus dependent CHD because these neonates can be saved and temporarily palliated till corrective surgery with prostaglandin E_1 infusion. The outcome may be potentially lethal if LV shows the complex myocardial changes and hypoplasia.

Investigations

Electrocardiograph

The ECG in AS has a low sensitivity and may be normal in a case with severe AS. In older infants and children, the resting ECG must be evaluated for age specific voltage criteria of left ventricular hypertrophy (LVH). The Holter monitoring of these patients may help in recognizing the dysrhythmias. The presence of arrhythmias predisposes for sudden cardiac death (SCD).

P wave is normal or bifid suggesting presence of mitral regurgitation. The QRS axis may be normal. The depolarization loop is clockwise with q waves seen in inferior leads— aVF III. LVH is represented by tall R wave in lead II, aVF , deep S in V_1 , tall R waves in V_{5-6} , and deeply inverted T waves also seen pointing against the QRS complex, so called wide QRS-T angle (**Fig. 3**).

In neonates and infants, there may be significant RVH and normal left ventricular forces. In infants having hypoplastic LV, R wave in left leads will be smaller. Increased left ventricular forces are not seen in neonatal period.

Radiology

Frontal projection of X-ray chest shows normal or minimally enlarged heart shadow in moderate to severe AS (**Figs 4A and B**).

12 lead ECG in patient with severe AS

Figure 3 ECG in severe aortic stenosis: Left ventricular hypertrophy (LVH) is represented by tall R wave in lead II and aVF , deep S in V_1 , tall R waves in V_{5-6} , deeply inverted T waves also seen pointing against the QRS complex, so called wide QRS-T angle. (Q wave changes are not seen in inferior leads)

Figures 4A and B Chest X-ray in aortic stenosis. (A) Dilated aorta in a 15-year-old patient with bicuspid aortic valve AS/AR; (B) X-Ray chest of a 4-day-old neonate with critical AS cardiomegaly and hepatomegaly. Pulmonary venous hypertension (PVH) cannot be appreciated in this over-exposed bedside film

Table 3 summarizes the findings associated with various levels of left ventricular outflow tract obstruction (LVOTO).

Echocardiography

Echocardiography in multiple views evaluates the LVOT and aortic root, the hemodynamic effect of AS, as well as presence and absence of associated lesions. Two-dimensional assessment (2-D mode) of aortic root is done at 4 levels: the annulus, the sinuses of Valsalva, sinotubular junction and the proximal ascending aorta. The parasternal long axis view is the best view to measure the aortic valve annulus and aortic root. Ascending aorta and arch can be measured in suprasternal long axis view. The valve morphology is best evaluated in 2D or 3D short axis parasternal view. Ascending aorta is evaluated in right high parasternal view and arch and descending aorta can be seen in suprasternal views. The major aortic abnormalities like progressive dilatation of aortic root, coarctation of aorta, dissection of aorta or carotid arteries must be looked for.

Doppler Echocardiography

Normally, blood flow across the aortic valve is laminar and peak systolic velocity of blood flow across the valve rarely exceeds 1.5 m/s. An aortic jet velocity greater than 4.0 m/s, Doppler gradient more than 40 mm Hg and aortic valve area less than 0.5 cm² suggests severe AS. The catheter derived peak-to-peak gradient is best corresponds with mean Doppler gradient and is the gold standard. The diastolic function of LV is assessed by MV inflow velocity graph and tissue Doppler assessment of mitral valve annular velocities.

Catheterization, CT and MRI

Diagnostic catheterization is rarely done; therapeutic catheterization is resorted to in appropriate cases. CT/MRI is done when aortic evaluation is required.

Role of Exercise Testing

Exercise testing can identify the limited exercise capacity and reveal symptoms in many (usually one-third) apparently asymptomatic children and adolescents. The one year prognosis of patients with a normal exercise test is excellent. In contrast, a positive exercise

test predicts the onset of a cardiac event in a sizeable proportion of patients. The advice for athletic activities can be made based on exercise testing.

Management

Medical Management

The decongestive management is needed for patients presenting with the left ventricular failure. The neonate presenting early may get benefit from prostaglandin infusion.

Balloon Dilatation

The balloon dilatation of aortic valve (BAV) or balloon aortic valvoplasty, first reported by Lababdi et al in 1984, is the safest and efficient method particularly for small infants who have limited options in absence of ideal size of prosthesis (**Figs 5A to C**). The balloon size used should not exceed the aortic annular size. The criteria for successful BAV result are: fall in gradient more than 50% of predilatation values, improved LV function and no more than minimal AR. The procedural success has been reported to be from 88 to 96%. The reported actuarial intervention-free rate after the 12 years is 60%. Optimal timing of ballooning is summarized in **Table 4**.

Surgical Interventions

The surgical options for infants and growing children, namely, open aortic commissurotomy, Ross procedure (**Fig. 6**) or valve replacement, are limited. AV replacement is usually management of choice in absence of a successful repair technique. The mechanical prosthetic replacement has shown acceptable long-term results but needs lifelong anticoagulation. Use of bioprosthetic valve (BPV) or tissue valves, homograft or heterograft, avoids the need for anticoagulation but less durability of prosthesis and chances of early reinterventions, are unresolved issues related to their use. The immediate results of Ross commissurotomy are good. The reported postoperative mortality is 5–20%. About 75% of tissue valves may need reintervention. The reoperation rate for mechanical prosthetic replacement is 55–90% on 15 years follow-up. Though BAV is the first line of management for the neonatal AS, modified Norwood operation may be the only treatment strategy for neonate with critical AS and concomitant LV hypoplasia.

Outcome

The outcome of bicuspid aortic valve depends on evolution of stenosis/regurgitation, aortic root dilatation and onset of infective endocarditis (IE). Infants with AS presenting early have more severe stenosis and higher mortality with or without treatment. But, beyond infancy, the mean age of death due to AS is 35 years. Cause of death is usually sudden cardiac death (SCD) in about 50% cases. The progressive LV dysfunction and congestive heart failure (CHF) is the cause of death in other 50% cases. AS is a progressive disease and patient with mild obstruction may also show increment in gradient later in life. The dilatation of aortic root beyond 45 mm makes it vulnerable for aortic dissection or rupture. The risk of IE associated with diseased aortic valve is more prevalent in young male and in patients with severe AS.

SUPRAVALVAR AORTIC STENOSIS

Supravalvar aortic stenosis (SVAS), a rare cause of AS, manifests as focal or diffuse narrowing of sinotubular junction and the ascending aorta. SVAS is often associated with Williams syndrome. Williams-Beuren syndrome with associated SVAS is known to be

Table 3 Summary and interpretation of radiological findings in aortic stenosis

Classical findings (All types of AS)	Frontal X-ray chest—normal or minimally enlarged heart shadow in moderate to severe AS; cardiac apex—rounded apex, displaced left and down in PA view, posterior displacement of cardiac shadow is seen in left lateral view
Enlarge RA, RV dominance	In neonates in critical AS (+/- hypoplastic LV, TR, MR)
Enlarged LA	LV dysfunction, associated PDA. Mitral regurgitation
Pulmonary venous hypertension	Critical AS; classical pulmonary edema in severe AS and LV failure
Dilated aorta	Valvar AS usually with bicuspid valve with or without AR
Inconspicuous ascending aorta	Associated supravalvar AS, infants and small children
Calcified valve	Elderly patients with AS
Evidence of operated or unoperated CHD	Subvalvar AS

Figures 5A to C Balloon aortic valvoplasty. (A) Partially inflated balloon; (B) Inflated balloon with waist remaining; (C) Balloon placement

Table 4 Valvar aortic stenosis: Timing of intervention

For infants and older children
<ul style="list-style-type: none"> • Left ventricular dysfunction: Immediate intervention by balloon dilatation, irrespective of gradients (Class I) • Normal left ventricular function: Balloon dilatation if any of these present: (i) gradient > 80 mm Hg peak and 50 mm Hg mean by echo-Doppler (Class I); (ii) ST-T changes in ECG with peak gradient of > 50 mm Hg (Class I); (iii) symptoms due to AS with peak gradient of > 50 mm Hg (Class IIa). In case of doubt about severity/symptoms, an exercise test may be done for older children (Class IIb)
For neonates
Balloon dilatation if symptomatic or there is evidence of left ventricular dysfunction/mild left ventricular hypoplasia (Class I), or if Doppler gradient (peak) > 75 mm Hg (Class IIa)

due to microdeletion in the elastin gene located at chromosome 7q11.23, inherited as an autosomal dominant disorder with variable penetrance in families.

Pathophysiology

Supravalvar aortic stenosis has three forms (1). The most common classical hour glass type presenting with focal narrowing of STJ and proximal aorta; (2) Membranous diaphragm at STJ but no narrowing outside; (3) Diffuse variety involving ascending aorta, arch vessels and may be associated with coarctation of aorta. The usual pathological changes are seen in media and intima. There may be smooth muscle hypertrophy, abnormal elastic fibers or varying degree of collagenization of media. It may also involve AV and coronary ostium and may present with ostial stenosis or dilatation of coronary artery. Stenosis of peripheral arteries like renal and mesenteric artery may be seen in 30% cases.

The resistive aortic flow and systolic hypertension of ventricle is common physiological effect of SVAS. There might be associated valvar AS and bicuspid AV in about 50% cases and subvalvar stenosis in about 16% cases.

Clinical Features

The special dysmorphic features of Williams syndrome associated with SVAS are small upturned nose, long philtrum, wide mouth, full

Figure 6 Ross procedure: excision of diseased aortic valve and placement of pulmonary autograft (blue). A valved conduit is placed to reconstruct right ventricular outflow tract (RVOT)

lips (**Fig. 3**). Mostly, there is the marked increase in the pressure of pulse of right upper limb (asymmetrical pulse in upper limb), an important clue to clinical diagnosis. This is known as *Coanda effect* and happens due to preferential flow of blood towards right upper limb. The precordial findings are almost similar to valvar AS (**Table 2**). Additionally, there might be bruit over peripheral arteries suggesting stenosis of the arteries. Children with coronary ostial stenosis may present with typical angina. It is difficult to differentiate level of LVOT obstruction on the basis of ECG or X-ray chest (**Table 3**). However, dilated aorta seen in X-ray chest of the patient with valvar AS is almost never seen in patients with SVAS (**Fig. 4**).

Treatment

Essentially, treatment of SVAS is surgery in symptomatic patients who have mean LVOT gradient 50 mm Hg or above.

SUBVALVAR AORTIC STENOSIS

Subvalvar aortic stenosis (SAS) is usually a progressive anatomical obstruction leading to the fixed LVOTO. SAS often has a dynamic component contributing to the obstruction.

It usually is an acquired lesion rarely presenting during early childhood. The abnormal flow pattern of blood has been credited for SAS in these patients. Common associations (present in 20–25% cases) are ventricular septal defect, atrioventricular septal defect, patent ductus arteriosus and bicuspid aortic valve, Shone complex, interrupted aortic arch and persistent left superior vena cava.

Diagnosis

The precordial findings, ECG, and X-ray chest are described in **Table 3**. The 2D, 3D transthoracic or transesophageal echocardiography with color and spectral Doppler are diagnostic; it evaluates its anatomical and functional aspects as well as the role of dynamic component. Additional information may be obtained by CT angiography and MRI.

Treatment

Medical Management

The β -blockers and calcium channel blockers help in reducing the contractility and hence they reduce dynamic component of the obstruction. Also, maintaining good hydration is important.

Surgery

Surgery is the treatment of choice for significant SAS. For hypertrophic cardiomyopathy, septal ablation is an alternative treatment. There are various surgical methods according to the type of SAS. Mitral valve replacement or repair may be needed in selected group of patients.

Shone's Complex

Described by Shone et al, in 1963, this complex is a constellation of left sided obstructive lesions which includes (1) Parachute MV; (2) Supra mitral ring; (3) Subaortic stenosis; and (4) Coarctation of aorta. The clinical presentation varies according to the severity of lesions. Therefore, management has to be customized and overall outcome cannot be predicted. The clinical deterioration of babies due to CHF and circulatory failure is common in first few weeks of life. Those infants presenting with severe LVOTO have high mortality, morbidity, and high rate of reinterventions.

IN A NUTSHELL

1. Aortic Stenosis refers to a fixed left ventricular outflow tract obstructive lesion at the level of aortic valve (valvar AS), above (supravalvar AS) or below (subvalvar AS). At times obstruction of left ventricular outflow tract may be present at more than one level.
2. Aortic stenosis can present in neonatal period, remain asymptomatic, or present anytime in childhood.
3. In older children, exertional dyspnea, angina pectoris, and syncope are the characteristic features in moderate to severe stenosis.
4. The aortic valvar stenosis is the most common, while subaortic and supravalvar aortic stenosis are infrequent and they rarely manifest in early infancy. Balloon valvuloplasty is the treatment of choice with excellent outcome.
5. The supravalvar stenosis is usually suspected when child has certain dysmorphic facial features suggestive of William syndrome. Long-term outcome of the isolated, nonsyndromic focal SVAS are more or less excellent.

Chapter 40.20

Clinical Approach to Infants and Children with Cyanotic Congenital Heart Disease

M Zulfikar Ahamed

Recognizable cyanosis is due to a reduced hemoglobin (Hb) content of more than 4–6 g/dL in capillary blood. With a normal or high Hb content, desaturation will produce a significant amount of reduced Hb to cause cyanosis, while in severely anemic infant, even in the presence of desaturation; reduced Hb will not reach the value to cause clinical cyanosis.

Recognizing central cyanosis in an infant, especially a neonate is quite tricky. Ambient light, wall paint, skin color and examiner's experience are some of the factors determining accurate detection of cyanosis. In a fair-skinned child, saturation below 85% is required to produce clinical cyanosis. If any baby is really blue, its saturation will be usually around 70%.

Situation	Saturation
Arterial desaturation	< 95%
Hypoxemia	< 90%
Clinical cyanosis	< 85%

CENTRAL CYANOSIS: A CLUE TO CONGENITAL HEART DISEASE

Central cyanosis in a heart disease is due to a right to left shunting either intracardiac or extracardiac. To put it in a different way, congenital cyanotic heart diseases are anomalies in which some systemic venous return will inevitably reach the systemic circulation without passing through lung. There are however many potential pitfalls in clinical recognition of congenital cyanotic heart disease.

- Clinical assessment of cyanosis can be inaccurate depending on hemoglobin status.
- Congenital cyanotic heart disease with increased pulmonary blood flow due to admixture physiology can have saturations varying from 85% to 90% so that there is no clinically evident cyanosis.
- Some acyanotic congenital heart disease (CHD), especially large left to right shunts can develop severe chest infection and CHF and cause central cyanosis.
- Primary lung conditions sometimes can mimic cyanotic heart disease.

Cyanosis in a cyanotic CHD is often uniform and constant. Occasionally, differential cyanosis can occur—upper limbs are pink and lower limbs are blue or alternatively, upper limbs blue and lower limbs pink. Clinical differential cyanosis requires at least a difference of 10% saturation between upper limbs and lower limbs. Causes are listed in **Table 1**.

CONGENITAL CYANOTIC HEART DISEASE IN INFANCY AND CHILDHOOD

Majority of infants and children with congenital cyanotic heart disease (CCHD) present with history of cyanosis—on crying or at rest. A few infants present for the first time with cyanotic spells. Occasionally, a child with CCHD will present with a cerebrovascular accident or brain abscess.

Table 1 Causes of differential and differential reversed cyanosis

Differential cyanosis	
Pink upper limbs and blue lower limbs	<ul style="list-style-type: none"> • Patent ductus arteriosus (PDA) with Eisenmenger syndrome • Persistent pulmonary hypertension (PPHN) in neonate • Hypoplastic left heart syndrome (HLHS) • Interrupted aortic arch syndrome (IAAS)
Reversed differential cyanosis	
Blue upper limbs and pink lower limbs	<ul style="list-style-type: none"> • Transposition of great arteries (TGA) with PDA with/without CoA

Note: PDA with Eisenmenger syndrome need not have differential cyanosis if it has associated atrial septal defect (ASD) or ventricular septal defect (VSD).

Cyanotic children may be classified into those who have decreased pulmonary blood flow (\downarrow PBF) or those with increased pulmonary blood flow (\uparrow PBF). CCHD with reduced PBF can be further categorized into two major groups: (a) With pulmonic stenosis; and (b) With pulmonary hypertension. Both effectively reduce blood flow across lungs and cause central cyanosis. There is a right to left intracardiac shunt at some level. Some infants with secondary pulmonary hypertension may have initial history suggestive of increased PBF.

Pulmonic stenosis most often occurs in association with ventricular septal defect (VSD). Majority of children with CCHD with reduced PBF have an interventricular communication and some degree of pulmonary stenosis (PS). Tetralogy of Fallot (TOF) is the prototype of this group. In some, PS is associated with intact IVS (inter ventricular septum) and right to left shunt occurs through a small atrial septal defect (ASD) or patent foramen ovale (PFO).

GROUP I CCHD

Decreased Pulmonary Blood Flow; PS with VSD

The common lesions in Group I are:

1. Tetralogy of Fallot (TOF)
2. Pulmonary atresia with VSD
3. Tricuspid atresia
4. Double outlet RV (DORV). VSD. PS
5. L-TGA. VSD. PS (Corrected TGA)
6. D-TGA. VSD. PS
7. AV septal defect with PS
8. Single ventricle with PS
9. Truncus arteriosus with PS.

Almost all of them share clinical features (**Table 2**) like deep central cyanosis, absent features of congestive heart failure (CHF), normal or near normal cardiac size, single S2 and an outflow murmur. Some may have some deviation from the set pattern, which may help in reaching a more specific diagnosis. Electrocardiography will be variable and is of greater use in differentiating between individual CHD among this group. Salient clinical features of individual conditions in Group I (CCHD; \downarrow PBF; PS with VSD) are outlined below:

Pulmonary atresia with VSD There is no outflow murmur; instead children will have a high volume pulse, a murmur of either patent ductus arteriosus (PDA) or main aorto pulmonary collateral arteries (MAPCA) or occasionally an ejection click due to dilated aorta.

Table 2 Characteristics of Group I CCHD with ↓PBF; PS with VSD

Characteristic history	Physical findings
Progressive central cyanosis from infancy resulting in deep cyanosis	No signs of CHF; JVP is usually not elevated
Hypercyanotic spells in infancy	No cardiomegaly
Squatting in childhood	Quiet precordium devoid of left parasternal heave or hyperkinetic impulses
No recurring chest infections	Single S ₂ (Second sound)
No history suggestive of CHF	An outflow systolic murmur of varying intensity
Progressive central cyanosis from infancy resulting in deep cyanosis	
Hypercyanotic spells in infancy	
<i>Chest X-ray</i>	
Normal cardiothoracic ratio, pulmonary oligemia, small sized pulmonary arteries, right-sided aortic arch (sometimes); 25–30% in TOF and in PA with VSD.	
<i>Electrocardiography</i>	Variable (Refer Table 3)

Abbreviations: CCHD, congenital cyanotic heart disease; PBF, pulmonary blood flow; PS, pulmonary stenosis; VSD, ventricular septal defect; CHF, congestive heart failure; JVP, jugular venous pressure; TOF, tetralogy of Fallot.

Tricuspid atresia will have a very early presentation with deep cyanosis, absent right ventricular impulses, prominent 'a' wave in jugular venous pressure (JVP) and sometimes a left ventricular apical impulse.

DORV. VSD. PS Clinically indistinguishable from TOF.

L-TGA. VSD. PS More often associated with dextrocardia; shares all the clinical features of TOF but for a very loud single S₂ at pulmonary area due to a L-posed anterior aorta. There could be an apical murmur-MR like, due to left AV valve (Tricuspid) regurgitation.

D-TGA. VSD. PS will have intense, early onset cyanosis from newborn days onwards and outflow murmur. There could be mild cardiomegaly.

AV septal defect with PS can have an LV impulse, an apical murmur due to left AV valve regurgitation (Mitral) in addition to RVOT murmur and a S₃.

Single ventricle with PS will be almost be like TOF; there could be an LV apical impulse, mild cardiomegaly and a long systolic murmur in spite of significant cyanosis.

Chest X-ray

Both TOF and PA with VSD will have right aortic arch in 25–30% of cases; Tricuspid atresia will have no upturned apex but will have prominent right atrium. L-TGA will have an L-posed aorta forming upper part of cardiac border. D-TGA will have prominent right atrial enlargement (RAE).

ECG

Findings include RAD, and RVH without strain. TOF will have early transition in precordial leads. RAE is not a feature in this group. The individual lesions will have certain characteristic ECG abnormalities (Table 3).

GROUP II CCHD

Severe PS; Intact Interventricular Septum (IVS)

Severe valvar PS in the long run can progress and cause raised filling pressures in right ventricle, which is transmitted to right atrium. If there is a PFO or ASD, right to left shunt occurs through it and causes central cyanosis later. Right ventricle dilates and develops dysfunction causing considerable cardiac enlargement. The clinical presentation is unique among CCHD with decreased PBF.

These children will have central cyanosis, elevated JVP with prominent a wave and v waves, cardiomegaly, hyperdynamic precordium, significant parasternal heave, single S₂ or wide split with delayed soft P₂, and S₃. Murmurs occur due to tricuspid regurgitation (TR) and PS. TR murmur may be more prominent!

ECG will show severe RVH with strain pattern. This is in contrast to TOF situation where there is no RV strain pattern as RV is used to systemic pressures from outset. RV pressure in this group can be suprasystemic causing a qR in V1 or V3 R. RV strain is evident with ST – T changes in V1-V6.

GROUP III CCHD

Decreased PBF with Pulmonary Artery Hypertension (PAH)

Just as PS causes impedance to right ventricular blood flow to lungs, severe PAH due to pulmonary vascular occlusive disease (PVOD)

Table 3 ECG findings in CCHD with decreased pulmonary blood flow (PBF); VSD with PS

	P wave	PR	QRS axis	RVH	LVH	BVH
TOF	N	N	RAD	++	—	—
PA/VSD	N	N	RAD	++	—	—
TA	RAE	N	LAD	0	++	
DORV	N	Prolonged	RAD-extreme	++	—	+
L-TGA	N	Prolonged	LAD	++	—	—
D-TGA	RAE	N	LAD	++	—	—
AVSD	RAE	Prolonged	LAD	±	—	+
Single ventricle	N	N	LAD ?	±	—	+
Truncus	N	N	RAD	+	—	+

Abbreviations: CCHD, congenital cyanotic heart disease; PBF, pulmonary blood flow; PS, pulmonary stenosis; VSD, ventricular septal defect; TOF, tetralogy of Fallot; D-TGA, D-transposition of great arteries; PS, pulmonary stenosis; DORV, double outlet RV; RAD, right axis deviation; LAD, left axis deviation; RVH, right ventricular hypertrophy; LVH, left ventricular hypertrophy; RAE, right atrial enlargement.

will cause considerable impedance to blood flow to lungs causing reduced pulmonary flow. A communication between chambers at any level will set up a right to left shunt causing central cyanosis. The classical condition, Eisenmenger syndrome, which is defined as a condition in which a left to right shunt develops severe PVOD so that bidirectional or right to left shunt occur causing central cyanosis.

Eisenmenger reaction can occur in ASD, VSD, PDA and AP window. Except ASD all Eisenmenger conditions behave similarly clinically. They will start as significant left to right shunt in infancy and develop cyanosis in the 2nd or 3rd decade, will have mild to moderate cyanosis, minimal or no cardiomegaly, no CHF and clinical findings of severe PAH which include parasternal heave, palpable P₂, loud and single S₂, ejection murmur and early diastolic murmur from pulmonary area and no murmur from shunt lesion. ASD will have slightly differing clinical presentation—prominent JVP, cardiomegaly, hyperdynamic precordium and in a majority, split S₂ with loud P₂.

ECG in all conditions will show right axis deviation, right ventricular hypertrophy without strain pattern. qR in V1 or V3 is unlikely as RV pressure seldom crosses systemic levels.

GROUP IV CCHD

Increased PBF: Parallel Circulation

Transposition of great arteries (TGA) is the unique CHD belonging to this group. It will present with severe cyanosis and mild CHF—especially TGA with intact IVS. Clinical findings will be intense early cyanosis, mild cardiomegaly, mild CHF and minimal or no murmur. Murmur in this group will be due to associated PS, small VSD or PDA. Chest X-ray will show mild-moderate cardiomegaly, right atrial enlargement, RV contour, increased pulmonary vascular with narrow base.

ECG will show monotonous findings—right ventricular hypertrophy with RAD.

D-TGA with large VSD will behave with more CHF, severe PAH and less intense cyanosis. Similar clinical picture can occur in DORV. Subpulmonic VSD and PAH (Taussig-Bing anomaly).

GROUP V CCHD

Increased PBF: Admixture Lesions

If there is a complete mixing of systemic and pulmonary venous return due to a common mixing chamber, admixture lesions result. Single atrium, single ventricle and truncus arteriosus are the classical lesions. Total anomalous pulmonary venous connection (TAPVC) and DORV. VSD and PAH also belong to this group. Presentation includes CHF in infancy, mild cyanosis, cardiomegaly with hyperdynamic heart, evidence of PAH, abundant murmurs—systolic and diastolic; and growth failure. Clinically, they will behave similar to a large left to right shunt with mild cyanosis.

ASD like presentation; CHF; Cyanosis	- TAPVC. Single atrium
VSD like presentation: CHF; Cyanosis	- Single ventricle. DORV
PDA like presentation: CHF; Cyanosis	- Truncus

All these lesions will cause cardiomegaly and plethora of lung fields. TAPVC and single Atrium (pretricuspid lesions) will have significant right atrial enlargement. Post-tricuspid lesions—Single ventricle, DORV and Truncus will have LA enlargement or biatrial

enlargement. Truncus will have a right sided aortic arch in 40–50% of cases.

ECG in pretricuspid admixture lesions will have right axis deviation, right ventricular hypertrophy and frequently RSR pattern in V1 or V3R. In post-tricuspid lesions RAD, BVH are common.

Other CCHD

Some congenital heart diseases defy categorization in to any of the above groups. They include Ebstein anomaly, pulmonary AV fistula (PAVF). Ebstein anomaly will have early cyanosis, cardiomegaly, prominent JVP, split S₁ and S₂, S₃ and S₄ and murmurs. In ECG, Ebstein will show RAD, VSR or splintered QRS in V1-V2, occasionally WPW (Rt) syndrome. RVH is the exception. CXR will reveal cardiomegaly, pulmonary oligemia and right atrial enlargement. PAVF is a curious clinical entity which presents as cyanotic infant or child with minimal or no cardiac findings. CXR and ECG are most often normal. Echocardiographic anatomy of heart is also normal. A contrast echocardiography and later a pulmonary angiography needed to clinch the diagnosis. Salient features of TOF like clinical conditions with specific clinical findings are listed in **Table 4**.

CYANOTIC HEART DISEASE IN THE NEONATE

They will have resting saturation of less than 94% PO₂ of less than 75 mm Hg. The common CCHD and increased PBF in newborn are pulmonary atresia with VSD, severe TOF, and tricuspid atresia, pulmonary atresia with intact IVS, Ebstein anomaly and severe critical PS with reversal of atrial level. The common CCHD with increased flow in the neonate are truncus arteriosus, DORV, VSD, PAH, TAPVC and single ventricle. Simple TGA presents with intense cyanosis and is perhaps the most common CCHD in the new born period. PPHN is a major cause of central cyanosis in the neonate. A simple schema is available to identify CCHD in the neonate based on CXR and ECG (**Table 5**).

IN A NUTSHELL

1. Cyanotic children are first classified into those who have decreased pulmonary blood flow (↓PBF) or those with increased pulmonary blood flow (↑PBF). CCHD with reduced PBF can be further categorized into two major groups: (a) With pulmonic stenosis; and (b) With pulmonary hypertension.
2. CCHD can be further grouped in 5 distinct clinical presentations as follows:
 - a. *Group I:* Decreased PBF; PS with VSD (TOF)
 - b. *Group II:* Decreased PBF: Severe PS, intact interventricular septum (Valvar PS)
 - c. *Group III:* Decreased PBF, Pulmonary hypertension (Eisenmenger syndrome)
 - d. *Group IV:* Increased PBF, parallel circulation (TGA)
 - e. *Group V:* Increased PBF, admixture lesions (TAPVC).

Chapter 40.21

Tetralogy of Fallot and Variants

Anita Saxena

Tetralogy of Fallot (TOF) is the most common cyanotic congenital heart disease (CCHD) in patients beyond the neonatal period. It was named after Etienne-Louis Arthur Fallot, a French physician, who first described the anatomical details in 1888. TOF is characterized by four typical abnormalities, namely infundibular pulmonary stenosis (PS) or right ventricular outflow tract obstruction (RVOTO), large nonrestrictive subaortic ventricular septal defect (VSD), overriding aorta and right ventricular hypertrophy (RVH) (**Fig. 1**).

VARIANTS OF TETRALOGY OF FALLOT

Tetralogy of Fallot variants include other CCHDs associated with a nonrestrictive VSD and reduced pulmonary blood flow. These include (1) pulmonary atresia with VSD, (2) TOF with absent pulmonary valve, (3) TOF with atrioventricular septal defect (AVSD), and (4) TOF with double outlet right ventricle (DORV). This chapter deals with diagnosis and management of TOF and its variants.

CYANOTIC CONGENITAL HEART DISEASES WITH TOF PHYSIOLOGY

Other CCHDs like tricuspid atresia with PS (TAPS), single ventricle with PS (SVPS), Transposition of great arteries with VSD and PS (TGA,VSD and PS), corrected transposition of great arteries with VSD and PS (c-TGA,VSD and PS) and complex diseases such as heterotaxy syndrome associated with VSD and PS, are sometimes grouped together as TOF physiology. These will not be discussed in this chapter.

EPIDEMIOLOGY

Tetralogy of Fallot represents 5–10% of all CHDs. It is the most common cause of cyanosis beyond the first weeks of life. The natural history is quite variable; most cases are diagnosed early in life,

especially in western countries. In India and many other developing countries, it is not uncommon to see adolescents or adults with unrepaired TOF. It is estimated that as many as 7,500–9,000 babies are born with TOF every year in India. The sex distribution is nearly equal; a slight dominance is described for males.

ETIOLOGY AND RISK FACTORS

Chromosomal abnormality of 22q.11.2 deletion is present in 15% of TOF patients. The recurrent risk in siblings is approximately 2–3%, but increases to 8% if two or more siblings are affected. If one of the parents has TOF, the chance of having a baby with TOF is 3–4% in those without 22q.11.2 deletion. The other risk factors which may increase the chances of a baby born with TOF include maternal diabetes mellitus and consumption of retinoic acid or trimethadione during pregnancy. In vast majority of cases, however, the etiology remains unknown.

Syndromic TOF

In a small proportion of patients, TOF is seen in association with a cluster of noncardiac congenital abnormalities and hence these children are labeled as having syndromic TOF. The most common abnormality found in patients with syndromic TOF is micro deletion of 22q11.2, also known as DiGeorge syndrome or velocardiofacial syndrome. This syndrome is characterized by facial dysmorphism, neonatal hypocalcemia and several other defects. Another chromosomal abnormality in syndromic TOF is presence of Trisomy 21 or Down syndrome. In rare cases Edward syndrome (Trisomy 18) and Patau syndrome (Trisomy 13) may be associated with TOF. Nonsyndromic TOF is much more common and several gene mutations are being linked as the underlying etiology in these patients.

HEMODYNAMICS

All the four abnormalities described in TOF result from anterior and cephalad deviation of the outlet (infundibular) septum along with hypertrophied septoparietal trabeculations. The deviation of outlet septum results in narrowing of the infundibular region and a defect between the two ventricles. The VSD is malaligned due to the deviation of outlet septum causing aortic override. The pressures in right ventricle (RV) and left ventricle (LV) equalize due to a large VSD. This along with RVOTO results in RVH. Since the abnormality originates in fetal life, the flow across the right ventricular outflow tract and main pulmonary artery is reduced and hence pulmonary artery (PA) and its branches remain small or hypoplastic.

The blood flow increases across aortic valve dilating ascending aorta. In addition, inherent problems in the wall of the ascending aorta are described in patients with TOF. This further dilates aorta and may result in, at times, aortic regurgitation (AR). The degree of override of aorta varies from 20% to 90% and aortic root rotates rightward and clockwise. The aortic valve leaflet is in fibrous continuity with the anterior mitral valve leaflet as seen in normal population.

The degree of infundibular stenosis determines the clinical presentation. Associated valvar PS is also seen in a small proportion of cases. In extreme form of TOF, no antegrade flow occurs across the right ventricular outflow tract resulting in pulmonary atresia. Progression of infundibular stenosis to complete blockage of the orifice is well described in postnatal life. Peripheral pulmonary artery branch stenosis has been described in about 20–25% of patients with TOF. The stenosis often occurs at the ostia of left and right pulmonary arteries, the former is much more common. Constriction by ductus tissue at the site of ductal insertion in left pulmonary artery is responsible for most cases of ostial stenosis of left pulmonary artery.

Figure 1 Diagrammatic representation of heart in tetralogy of Fallot showing a large ventricular septal defect, right ventricular outflow tract obstruction, overriding of aorta and right ventricular hypertrophy. Abbreviations: AAo, ascending aorta; LA, left atrium; LV, left ventricle; PA, pulmonary artery; RA, right atrium; RV, right ventricle.

The VSD is large, nonrestrictive and is subaortic in location, rarely it may be doubly committed and subarterial due to complete absence of infundibular septum. This type of VSD is more commonly described from South-East Asian population. Additional muscular VSDs are seen in a minority of patients. In those with Down syndrome, the VSD is located in the inlet region as a part of AVSD.

ANATOMIC VARIANTS OF FALLOT TETRALOGY

Tetralogy of Fallot with Pulmonary Atresia

This is the most severe form of TOF. In this condition there is no antegrade flow across the pulmonary valve, either because of complete infundibular atresia or due to pulmonary valve atresia. The pulmonary arteries are small or even absent. In about half of the cases, pulmonary blood flow is derived from patent ductus arteriosus and these usually have well-formed central pulmonary arteries. In the remaining half, the pulmonary blood flow is derived from systemic-to-pulmonary collaterals and central pulmonary arteries may be very small, seagull like, or completely absent. Large collaterals are also labeled as major aortopulmonary collateral arteries (MAPCAs) and these originate from descending thoracic aorta. Aortopulmonary collateral arteries can also arise from subclavian arteries. Large collateral arteries usually supply different segments of lungs with almost no overlap of blood supply. Stenosis in the course of collateral arteries is usual, thus protecting lungs against exposure to high systemic pressures.

Tetralogy of Fallot with Absent Pulmonary Valve

In about 5% of cases of TOF, the pulmonary valve leaflet tissue is absent or rudimentary. The RVOTO in such cases is due to pulmonary annulus hypoplasia with mild or no infundibular stenosis. The main and branch pulmonary arteries are dilated and may be aneurysmal. The enlarged pulmonary arteries tend to compress over the tracheobronchial tree producing marked respiratory symptoms. The ductus arteriosus is almost always absent. Right aortic arch is more common than in TOF, seen in 50% of cases. Free pulmonary regurgitation is universal. Associated abnormalities of tracheobronchial tree, including weakness of walls of airways, are known to be associated further aggravating the respiratory symptoms in these patients.

Tetralogy of Fallot with Double Outlet Right Ventricle (DORV)

In this variant, the aortic override is more than 50%. More than half of aorta is committed to right ventricle. Moreover, there is tissue interposed between the aortic valve and the anterior mitral valve leaflet, resulting in discontinuity between the two structures. The physiology and hemodynamics are not very different from that of TOF; however, the surgical repair may be somewhat different. These patients are more prone to develop left ventricular outflow tract narrowing postoperatively.

Tetralogy of Fallot with Atrioventricular Septal Defect

This combination is seen in 2% of TOF patients, mostly in those with Down syndrome. The information is important when closing VSD at the time of surgical repair. The ECG may show left axis deviation, a typical finding for AVSD.

ASSOCIATED ANOMALIES

Coronary Artery Anomalies

Coronary anomalies are seen in 5–8% of patients, the most important being anomalous origin of left anterior descending

artery (LAD) from right coronary artery (RCA). This abnormality, seen in 3–4% of cases, is ominous as the anomalous LAD crosses the right ventricular outflow tract when coursing towards left ventricle and is likely to get injured at the time of surgical repair if right ventriculotomy is done. Single coronary artery is a less common anomaly associated with TOF and one of its branches may pose a similar challenge during surgery.

Aortopulmonary Collaterals

Classically described in patients with pulmonary atresia and VSD, aortopulmonary collateral is not uncommon in TOF, especially in unrepaired adult patients. These develop mostly from bronchial arteries, but are also seen from subclavian arteries and very rarely from coronary arteries. Significant collaterals need to be occluded in the catheterization lab prior to surgical repair of TOF. Aortopulmonary collaterals are a source of nuisance when dealing with older children and adults with TOF. They can result in hemoptysis. Collaterals are also a source of bleeding in the intra- and postoperative period after intracardiac repair for TOF.

Right Aortic Arch

Right-sided aortic arch is seen in 25% of patients with TOF. The branching pattern is mirror image of the normal. The prevalence is higher in pulmonary atresia with VSD.

Others

Associations such as discontinuous pulmonary arteries, unilateral absence of a pulmonary artery branch, additional muscular VSDs, etc., have significant bearing on planning the surgical repair. Atrial septal defect, patent foramen ovale, partial anomalous pulmonary venous connection are also known to be associated with TOF but are of minor significance.

CLINICAL FEATURES

Tetralogy of Fallot produces no symptom or sign in fetal life although it can be diagnosed in a fetus using echocardiography. In most patients, variable degree of cyanosis is noticed in first few months of life. However, presentation may be delayed to a much older age, more so in developing countries. At times the first presentation is in a cyanotic spell. Some of the patients may be completely acyanotic and asymptomatic as the RVOTO is not very severe and hence good pulmonary blood flow is maintained. Such patients are labeled as Pink TOF. The symptomatic status of the patient is primarily determined by degree of RVOTO.

Those with severe obstruction present early and sometimes present in a cyanotic spell. A cyanotic spell is seen in patients aged between 6 months and 2 years and is characterized by deepening of cyanosis, faster and deep acidotic breathing and excessive irritability. A severe episode can produce convulsions, unconsciousness and even death. The precipitating events include crying and defecation. Anemia is a very important and common underlying precipitating factor in Indian setup. Cyanotic spell occurs secondary to tachycardia, decreased peripheral vascular resistance and infundibular spasm. Even one episode of cyanotic spell should be considered very significant and indicates early intervention. Anemia must be corrected by transfusing whole blood. Diagnosing anemia in a cyanotic child can be difficult on physical examination and hemoglobin (Hb) estimation can also be misleading. Cyanotic patients require a higher Hb and therefore an Hb of less than 13–14 g/dL should be considered low.

Older children, generally above 2 years of age assume squatting posture to combat hypoxia. Squatting is a very typical symptom of TOF and helps child to get relief since squatting increases peripheral vascular resistance and decreases right to left shunting.

Squatting also decreases the unsaturated blood from legs to reach heart. Squatting generally disappears by 8–10 years of age. In older children and adults, exercise limitation and exertional dyspnea are main symptoms, primarily related to hypoxemia.

Rarely, patients present with cerebral stroke. Stroke occurs secondary to cerebral infarct or cerebral abscess. Infarcts are more likely in younger patients (< 2 years of age) and are generally associated with iron deficiency anemia. Brain abscess is seen in older children and adults, secondary to an infection since bacteria can cross from right side of the heart to the left side of the heart. Brain abscess must be suspected in an older child or adult having TOF and presenting with history of fever, headache, listlessness, vomiting, etc., even without clear-cut neurological deficit.

Physical Signs

The growth and weight gain is often normal. Varying degree of cyanosis is seen (except in Pink TOF patients). In patients with syndromic TOF, facial features of DiGeorge syndrome or Down syndrome may be obvious. Clubbing of fingers and toes is noticeable in cyanotic patients; advanced grades of clubbing are seen in older children.

Features of heart failure are absent. In older patients, a wave may be prominent in jugular venous pressure. The cardiac impulse is placed normally with no evidence of cardiomegaly. A right ventricular heave is absent or is very soft. Systolic thrill along upper and mid left sternal edge may be felt, especially in those with mild cyanosis. On auscultation, second sound is single and there may be a constant ejection click due to a dilated aorta. The classical finding is presence of an ejection systolic murmur at upper and mid left sternal border. The intensity and duration of the murmur is inversely proportional to the severity of cyanosis. The murmur intensity can change and it may be absent during a cyanotic

spell. It is important to understand that VSD does not produce any murmur in these patients as pressures in both ventricles are equalized. A continuous murmur is suggestive of pulmonary atresia with VSD. The murmur if heard at the upper left sternal border is due to a patent ductus arteriosus (PDA) and if heard at the right upper sternal border or over the back, then it is due to aortopulmonary collaterals. A to and fro murmur (ejection systolic and early diastolic) at upper left sternal edge is very suggestive of TOF with absent pulmonary valve syndrome.

NATURAL HISTORY

One year survival for unoperated patients of TOF is close to 70%. 10-year survival varies from 20–25%, however, only 6% survive beyond 30 years. The survival is much poorer for pulmonary atresia with VSD, only 8% survive beyond 10 years. The disease is generally progressive due to increasing infundibular stenosis. The compliance of the right ventricle reduces as age advances, further increasing the right to left shunting. Aortic regurgitation develops in 5–7% of patients, either due to a dilated aorta (caused by increased blood flow and medial weakness of aortic wall), large aortopulmonary collaterals, aortic valve prolapse (in those with sub arterial VSD) or secondary to infective endocarditis of aortic valve. These patients also develop complications like coagulopathies, hyperuricemia, and skin, pulmonary and renal abnormalities which are related to prolonged hypoxemia, cyanosis and polycythemia.

INVESTIGATIONS

ECG

Characteristic findings of TOF are right axis deviation and right ventricular hypertrophy (**Fig. 2**). The precordial leads typically show early transition in leads V1 or V2 and therefore recording of

Figure 2 Electrocardiogram showing right axis deviation, right ventricular hypertrophy and early transition of QRS complexes in precordial leads

V₄R lead is advisable. Patients with AVSD variant may show left axis deviation of the QRS axis. Wide QRS with right bundle branch block pattern is sometimes seen after complete repair of TOF.

X-ray Chest

Normal cardiac size with uplifted apex, typical of hypertrophied right ventricle along with concave pulmonary artery segment gives a typical contour to the heart shadow, called boot-shaped heart (**Fig. 3**). Those with right sided aortic arch show an indentation to the right of tracheal shadow. The lung fields are oligemic in cyanotic patients. Patients with TOF and absent pulmonary valve may show cardiomegaly with or without pulmonary plethora. The central pulmonary arteries are dilated in these cases.

Echocardiography

It is the most important diagnostic tool and must be performed for each case. It establishes the diagnosis and may be able to provide full preoperative information in infants and young children with good acoustic windows. The size, location of VSD is well defined (**Fig. 4**). One must be careful when excluding additional muscular VSDs by echo as color Doppler may not be useful since pressures in the two ventricles are equal (**Figs 5A and B**). The anatomy of the right ventricular outflow tract, sizes of pulmonary annulus, and main, right and left pulmonary arteries can also be adequately assessed (**Figs 6A and B**). The gradient across the right ventricular outflow tract is easily estimated by Doppler (**Fig. 7**). In young infants, it may be possible to define coronary anatomy (**Fig. 8**) and aortopulmonary collaterals. Echo is also very useful modality during cardiac surgery as intraoperative transesophageal echo is able to detect additional VSDs better. It also confirms adequacy of repair when performed after completing surgery. Echocardiography has an important role in long-term follow-up of operated patients, especially for sequential follow up to determine timing of pulmonary valve replacement.

Echocardiography in patients with TOF with absent pulmonary valve shows dilated proximal pulmonary arteries, rudimentary pulmonary valve with stenosis at annular level (**Figs 9A and B**). Significant pulmonary regurgitation is seen on color Doppler (**Fig. 10**).

Cardiac Catheterization and Angiography

Cardiac catheterization and angiography is required as a part of preoperative work-up of those patients in whom full information

is not obtained by echocardiography. Cardiac catheterization and angiography has the added advantage of providing hemodynamic data and details of coronary anatomy, aortopulmonary collaterals and additional VSDs. Filling pressures on right and left side of heart provide important information about the diastolic function of the cardiac chambers. Angiograms are made in right ventricle to define its size, function and to delineate infundibular stenosis, main and branch pulmonary arteries (**Figs 11A and B**). Left ventricular angiography defines subaortic VSD, additional VSDs (if present) and also the degree of aortic override (**Fig. 12**). Aortic root angiogram provides information about coronaries; their origin and course (**Fig. 13**) and aortic regurgitation. Aortopulmonary collaterals are seen on descending thoracic aortogram. In older children and adults, it may be better to do selective injection into subclavian arteries to exclude collateral from these vessels. Significant collaterals need to be occluded in the catheterization lab prior to surgical repair of TOF, by use of commercially available coils and/or other materials (**Figs 14A and B**).

Magnetic Resonance Imaging (MRI)

This investigation is rarely performed, except in patients with pulmonary atresia and VSD. In these patients, MRI defines aortopulmonary collaterals well, prior to unifocalization surgery. MRI is indispensable for follow up of postsurgical TOF patients. Right ventricular volume and function, and quantification of pulmonary regurgitation are best estimated serially by MRI. It also helps to determine the timing of pulmonary valve replacement in these patients. Unfortunately with the presently available machines, MRI takes long time for image acquisition and is therefore not very suitable for infants and young children who would need general anesthesia for performing MRI.

CT Angiography

With advances in CT equipment, CT angio can be done very fast and with lower doses of radiations. CT angio is a good preoperative investigation in select cases where information on echo is not complete. It can provide useful information on pulmonary artery anatomy, coronaries and aortopulmonary collaterals.

MANAGEMENT

Every patient with TOF needs surgical repair, although at times complex anatomy may prohibit complete intracardiac repair.

Medial Management

With advances in surgical techniques, surgery is now being offered to infants and small children. Therefore, the role of medical management is limited. However in countries like India where surgical facilities are not widely available, medial management assumes importance till the time patient is operated.

Intravenous Prostaglandin

Intravenous prostaglandin (PGE1) maintains patency of ductus arteriosus when used in newborns. Continuous infusion at a dose of 0.05–0.4 $\mu\text{g}/\text{kg}/\text{min}$ is very useful for neonates with pulmonary atresia and VSD who become hypoxemic due to ductal closure. The PGE1 infusion is continued to maintain pulmonary blood flow till a systemic to pulmonary artery shunt surgery is done. It is important to remember that PGE1 can produce apnea in 10–15% of babies and hence must be given carefully in hospital setting with facilities for assisted ventilation.

Figures 11A and B Right ventricular angiogram from two patients of tetralogy of Fallot. Tight infundibular stenosis (inf PS) with adequate sized pulmonary arteries is seen (A) (B) Filling of very small pulmonary artery branches. Note filling of aorta due to the presence of right to left shunting through the ventricular septal defect

Figures 14A and B Selective angiogram in an aortopulmonary collateral artery, before (A) and after (B) its occlusion with coils

Beta-blockers

These drugs are used to reduce heart rate and to relax dynamic component of infundibular stenosis. Propranolol is the most frequently used beta-blocker, the dose is 1–4 mg/kg/day in 3 divided doses.

Correction of Anemia

Iron supplements or even blood transfusion is necessary for correcting anemia which is a common finding in Indian setting.

Treatment of a Cyanotic Spell (Also see Chapter 40.38)

The spell should be managed as an emergency. Child is placed in a knee chest or squatting position and oxygen inhalation given. Morphine sulfate is injected intravenously (or subcutaneously if intravenous line is not available) in a dose of 0.1 mg/kg. Beta-blockers should be given intravenously. Propranolol or metoprolol may be used in a dose of 0.1 mg/kg, slow bolus. Heart rate and blood pressure should be monitored while giving beta-

blockers. The dose can be repeated after 5–7 min, if necessary. A vasoconstrictor drug such as phenylephrine is administered to increase peripheral vascular resistance, thereby decreasing right to left shunt. Child may be given sodium bicarbonate to counter acidosis. Intravenous fluids are given to expand volume; fluids can be given liberally since the risk of developing heart failure is almost negligible. If spell is still not aborted with these measures, child may be intubated and mechanically ventilated and urgent intervention performed.

Transcatheter Palliation

Some of the infants benefit from pulmonary valve balloon dilatation, especially if the RVOTO is both valvar and infundibular. Other modes of transcatheter treatment for select patients include stenting of ductus arteriosus (for pulmonary atresia variant) and stenting of right ventricular outflow tract. All these measures increase pulmonary blood flow instantly and give grace period before complete repair is undertaken.

Surgical Management

Complete surgical repair of TOF is the definitive treatment. The timing of complete intracardiac repair varies from center to center. If good surgical results can be attained with low operative mortality, morbidity, good medium and long-term outcomes, complete repair should be encouraged. However, a systemic to pulmonary artery shunt should be considered an option for infants and small children in centers where results of intracardiac repair are not optimal at this age. Management strategies producing the best outcome in their own institution should be pursued by treating physicians and surgeons.

Palliative Systemic Artery to Pulmonary Artery Shunt Procedure

In this procedure, an anastomosis is established between a systemic artery and same side branch pulmonary artery. The commonly performed shunt is Blalock-Taussig (BT) shunt, wherein subclavian artery is connected to ipsilateral branch pulmonary artery. This anastomosis may be direct (classical BT shunt) or by use of a Gore-Tex tube (modified BT shunt), modified BT shunt is usually performed these days. This procedure may be ideal for severely cyanosed patients, less than 4–6 months of age. The systemic saturation generally improves to over 80% following a BT shunt. BT shunts may also have to be done in older patients if the anatomy is not suitable for total repair. For example, in those with small pulmonary arteries, BT shunt helps in growth of pulmonary arteries. BT shunt is also indicated in children under 2–3 years of age who have an anomalous LAD from RCA and require transannular patch.

Total Intracardiac Repair

Although total repair can be done in neonatal period, most centers in India would do the repair in infants over 6 months or so of age. Elective repair in a stable patient can be performed at about one to one and a half years of age, at a body weight of over 7 kg. The VSD is closed using a patch; the muscle bundle in the infundibular region is resected to relieve RVOTO. Most of intracardiac repairs can be done using transatrial route combined with a transpulmonary approach and without the need of right ventriculotomy.

Patients with pulmonary atresia and sizable pulmonary arteries can undergo complete repair with the use of right ventricle to pulmonary artery conduit, along with closure of VSD. However cases where pulmonary arteries are absent or very small, the collaterals are used as pulmonary arteries and connected by a prosthetic tube to each other and to the right ventricle, this procedure is called unifocalization and may have to be performed in several stages. Surgical treatment of TOF with absent pulmonary valve usually requires a pulmonary valve replacement using a homograft and reduction of the dilated pulmonary arteries along with closure of VSD.

Surgical mortality for intracardiac repair is less than 2%. In some institutions it may be almost zero. Immediate and in-hospital

complications include development of complete heart block, atrial tachycardia, residual VSD, residual RVOTO, etc. Complete heart block is permanent in about 1% of patients operated for TOF requiring placement of a permanent pacemaker. Atrial tachycardia is treated with drugs; these are generally required for a short period. In view of increasing avoidance of right ventriculotomy, right bundle branch block pattern in the ECG is becoming less common.

LONG-TERM FOLLOW-UP

Long-term prognosis for patients operated for TOF is generally good; although survival is less than that of normal population (86% survival at 30 years). Pulmonary regurgitation is the major cause of late re-intervention. Pulmonary regurgitation results in right ventricular dilatation leading to impaired exercise tolerance, cardiac arrhythmia and increased risk of sudden death.

IN A NUTSHELL

1. Tetralogy of Fallot (TOF) is the most common cyanotic form of CHD.
2. The age at presentation varies depending upon the severity of RVOTO and degree of cyanosis.
3. Severe cyanosis may result in a cyanotic spell, which may be life-threatening.
4. The ECG and X-ray chest are quite characteristic and echocardiography is generally sufficient for defining the anatomy preoperatively.
5. In older children and adults, cardiac catheterization and angiography may be required prior to surgery.
6. Open heart surgery for intracardiac repair is the definite treatment.
7. In neonates and young infants, a palliative systemic to pulmonary artery shunt may have to be performed before a total repair can be undertaken.
8. In most instances long-term prognosis is good although lifelong follow-up is required.

Chapter 40.22

Tricuspid Atresia

P Syamasundar Rao

Tricuspid atresia (TA) is defined as congenital absence or agenesis of the tricuspid valve. It is the third most common cyanotic congenital heart defect (CCHD) and is the most common cause of cyanosis with left ventricular hypertrophy.

EPIDEMIOLOGY

The reported prevalence of tricuspid atresia is 1.4% of all congenital heart defects (CHD). With known prevalence of CHDs at 0.8% of livebirths, tricuspid atresia is likely to occur in roughly 1 per 10,000 livebirths with no reported regional differences in Western and South Asian countries including India. Racial predilection is also not evidenced from available reports. When there is no sex predilection in the overall occurrence of TA as a whole, a male preponderance (66% versus 34%) is evident when both TA and transposition of the great arteries (TGA) occur in the same child.

ETIOLOGY

The etiology of TA is likely to be multifactorial as in other CHDs, wherein exposure of a sensitive fetus (genetically predisposed) to an adverse environmental trigger during a critical period of cardiac morphogenesis causes the CHD. Extensive studies of gene mapping that are currently in progress may unravel previously unknown genetic mechanisms.

PATHOGENESIS

The tricuspid valve (TV) develops shortly after the division of the atrioventricular canal. The septal leaflet of the tricuspid valve develops mostly from the inferior endocardial cushion. The anterior and posterior tricuspid valve leaflets appear to develop by undermining of a skirt of ventricular muscle tissue. The undermining process extends until the atrioventricular valve junction is reached. Resorption of the muscle tissue produces normal-appearing valve leaflets and chordae tendineae. Complete fusion of valve leaflet components results in tricuspid atresia (TA) while its partial fusion causes tricuspid stenosis (TS). The stage of development of the embryo when the environmental insult occurs determines the formation of either a muscular type of TA (most common form) or well-formed but fused tricuspid-valve leaflets.

CLASSIFICATION

Based on the Valve Morphology (Proposed first by Van Praagh and subsequently modified).

The most common type of tricuspid atresia (89%) is muscular, and it is characterized by a dimple or a localized fibrous thickening in the floor of the right atrium at the anticipated site of the tricuspid valve. Other less common types are rare.

Classification Based on Pulmonary Vascular Markings on a Chest Radiograph (Proposed by Astley and modified later by Dick).

Group A: Decreased pulmonary vascular markings

Group B: Increased pulmonary vascular markings and

Group C: Transition from increased to decreased pulmonary vascular markings.

Classification Based on Great-Artery Relationships (Proposed by Kühne and subsequently expanded and revised by Edwards and

Burchell, Keith, Rowe, and Vlad and Rao)

Type I: Normally related great arteries

Type II: D-Transposition of the great arteries

Type III: Great artery positional abnormalities other than D-transposition of the great arteries

- *Subtype 1* L-Transposition of the great arteries
- *Subtype 2* Double outlet right ventricle
- *Subtype 3* Double outlet left ventricle
- *Subtype 4* D-malposition of the great arteries (anatomically corrected malposition)
- *Subtype 5* L-malposition of the great arteries (anatomically corrected malposition)

Type IV: Persistent truncus arteriosus.

All types and subtypes are subdivided into the following subgroups:

- *Subgroup a:* Pulmonary atresia
- *Subgroup b:* Pulmonary stenosis or hypoplasia
- *Subgroup c:* No pulmonary stenosis (normal pulmonary arteries).

After the above categorization, the status of the ventricular septum [intact or ventricular septal defect (VSD)] and the presence of other associated defects are described.

HEMODYNAMICS

The atretic tricuspid valve necessitates the flow of all systemic venous blood across the atrial septum into the left atrium, from where it passes through the mitral valve into the left ventricle. This pattern of flow is similar in all except in type III subtypes 1 and 5. In these subtypes, the atretic morphologic TV is on the left side because of inverted ventricles. Consequently, the pathophysiology is that of mitral atresia with left-to-right shunting of pulmonary venous return and subsequent mixing with systemic venous return.

In children with type I TA with normally related great arteries and a VSD, left to right shunt across the VSD provides pulmonary blood flow, whereas in the absence of a VSD, the pulmonary blood flow essential for the very survival of the child is derived via the patent ductus arteriosus or aortopulmonary collateral vessels. The systemic blood flow is derived directly from the left ventricle.

In children with type II TA with D-transposition of the great arteries, the pulmonary blood flow is derived directly from the left ventricle. The aorta receives blood from the right ventricle via the VSD and left ventricle.

In other types of TA, the systemic and pulmonary artery flow are dependent on the ventriculoarterial relationship and the size of the VSD. Arterial desaturation occurs secondary to complete admixture of both pulmonary and systemic venous returns in the left atrium. Other physiologic principle includes volume overload of the left ventricle that has to supply the systemic, coronary and pulmonary circulations. Quantity of pulmonary blood flow is the main determining factor of the clinical presentation and subsequent therapeutic interventional measures.

It becomes absolutely essential to remember that the clinical features of TA are further influenced by the changing hemodynamics seen in growing infants. These include: (A) spontaneous closure of the ductus arteriosus causing pulmonary oligemia and systemic hypoxemia; (B) development of restriction of the interatrial communication, causing systemic venous congestion; and (C) spontaneous diminution or even complete closure of a VSD which may decrease pulmonary blood flow with consequent systemic hypoxemia in type I patients or produces subaortic (i.e., systemic) outflow obstruction in type II patients.

CLINICAL FEATURES

Nearly 50% of children with TA present with symptoms on their first day of life and 80% become symptomatic by the end of one month. The amount of pulmonary blood flow mainly determines the clinical features and the age of presentation.

Infants with Decreased Pulmonary Blood Flow

These children present with cyanosis in the first few days of life; the lesser the amount of pulmonary flow, the earlier the infant presents with cyanosis. Hyperpnea with acidotic breathing is often seen as presenting features besides cyanosis in these neonates with markedly decreased pulmonary blood flow. Most of these neonates are of type Ib classification mentioned above. In the presence of pulmonary atresia is (subgroup a), cyanosis gets manifest as the ductus begins to close.

Physical examination shows central cyanosis, tachypnea or hyperpnea, normal pulses, and no hepatomegaly are the usual features. The precordium is quiet without any thrills on palpation. On auscultation, the second heart sound is single, and a holosystolic murmur, suggestive of VSD is heard at the lower sternal border. Diastolic murmurs are not usually present. In cases with pulmonary atresia, no holosystolic murmur is heard, and a continuous murmur of patent ductus arteriosus is rarely heard. It is of note that signs of heart failure are absent.

Patients with Increased Pulmonary Blood Flow

These children present with symptoms suggestive of congestive heart failure, namely, dyspnea, fatigue, difficulty in feeding, and perspiration. Other modes of presentation are failure to thrive and recurrent respiratory tract infection. These symptoms usually occur within several weeks of life; however, some babies may present within the first week of life. Most of these babies belong to type IIc (i.e., transposition of the great arteries without pulmonary stenosis, but with VSD); some may be of type Ic (i.e., normally related great arteries and no pulmonary stenosis and a large VSD). Some babies with type II defect may have coarctation of the aorta and in such a situation the onset of congestive heart failure is early.

Physical examination reveals an infant with tachypnea, tachycardia, minimal cyanosis (if any), decreased femoral pulse (in the presence of aortic coarctation), hyperdynamic precordial impulses, single or split second heart sound, a third heart sound at the apex, holosystolic murmur of VSD at the left lower sternal border and a mid-diastolic rumble at the apex. Clinical signs of congestive heart failure are usually seen.

Other Features

In both the above two groups, prominent a waves in the jugular venous pulse along with prominent hepatic pulsation may be seen if clinically significant interatrial obstruction is present.

In a few patients who have balanced circulation without significant pulmonary oligemia or plethora, the presentation may be delayed and may present later with either a murmur or cyanosis.

Untreated patients may present with clubbing, polycythemia, stroke, brain abscess, coagulation abnormalities, and hyperuricemia; these are not too dissimilar to those seen in other cyanotic congenital heart defects. Older children and adolescents (and even adults) may present with atrial arrhythmias (flutter and/or fibrillation).

APPROACH TO DIAGNOSIS

A diagnosis of TA may be entertained by correlation of history of presentation with elicited clinical features and investigative

tools—chest X-ray and electrocardiogram (ECG) with subsequent confirmation by echocardiographic evaluation.

Chest X-ray

Its usefulness is in evaluating the pulmonary blood flow pattern and thus categorizing the index case to either CCHD with decreased pulmonary blood flow (oligemic lung fields) or CCHD with increased pulmonary blood flow (plethoric lung fields). In children with decreased pulmonary blood flow, the heart is normal in size or minimally enlarged. Concavity in the region of the pulmonary artery segment is seen in patients with a small pulmonary artery or pulmonary atresia. If pulmonary blood flow is increased, cardiac enlargement is seen.

Electrocardiogram

In an infant with cyanosis, ECG is virtually diagnostic of tricuspid atresia (**Fig. 1**). An abnormal and superiorly oriented major QRS vector, the so-called left axis deviation in the frontal plane, left ventricular hypertrophy, and decreased right ventricular forces are seen. Right atrial hypertrophy, evidenced by tall and peaked P waves (≥ 2.5 mm) in lead II and right chest leads may be present.

Echocardiogram and Doppler

Apical four-chambered and subcostal views help to identify the atretic tricuspid valve (TV), seen as a dense band of echoes at the site where the TV ought to be (**Figs 2A and B**); the right atrium, left atrium and left ventricle are enlarged whereas the right ventricle is usually small. The size of the left atrium and the size and function of the left ventricle can be assessed by echo studies.

Right to left shunt across the patent foramen ovale is seen by color Doppler imaging (**Fig. 3**). As mentioned above, TA is classified based on the relationship of the great arteries. Great artery relationship is established by following the vessel until bifurcation (**Figs 4A and B**) or aortic arch. In patients with normally related great arteries (type I), the VSD provides blood flow into the lungs (**Figs 5A to C**) while in those with associated transposition (type II), the VSD provides systemic flow.

Doppler Interrogation (Pulsed, Continuous Wave and Color Doppler)

It is also useful in demonstrating left to right shunt across the VSD (**Fig. 5**). Peak Doppler flow velocity across right ventricular outflow tract will help in identifying obstruction across these sites. As VSD may be small to cause obstruction to systemic flow, assessment of the size of VSD by 2D and color Doppler, pulsed and continuous wave Doppler is of paramount importance in type II patients. Imaging and Doppler from suprasternal notch view may show aortic coarctation (**Figs 6A and B**), which is more common in type II patients with transposition of the great arteries. The echo-Doppler findings are sufficiently characteristic for TA and therefore, cardiac catheterization and selective cineangiography are not needed for its diagnosis.

Other Laboratory Studies

Pulse oximetry measures systemic arterial oxygen saturation and is a useful adjunct in the clinical assessment. O_2 saturations in high 70s to low 80s are considered appropriate for tricuspid atresia. Arterial blood gases, in addition to assessment of oxygenation status, provide ventilatory status (i.e., PCO_2), and metabolic status (i.e., base deficit). Hemoglobin and hematocrit measurements along with RBC indices help to assess whether iron-deficiency anemia is present. Serum electrolytes are particularly useful in children receiving diuretics.

Figure 1 ECG of infant with tricuspid atresia showing abnormal, superiorly oriented mean QRS vector in frontal plane (-45° , left axis deviation), left ventricular hypertrophy, and diminished anterior (R waves in leads V1 and V2) and rightward (S waves in leads V5 and V6) forces. Prominent P waves, indicative of biatrial enlargement are also seen in several leads

Figures 2A and B Selected video frames from apical four-chamber, 2-dimensional echocardiographic views of a baby with tricuspid atresia demonstrating an enlarged left ventricle (LV), a small right ventricle (RV) and a dense band of echoes at the site where the tricuspid valve echo should be (ATV) (thick arrow) with closed (A) and open (B) mitral valve. A moderate sized ventricular septal defect (VSD) (thin arrow) is shown
Abbreviations: LA, left atrium; RA, right atrium.

Cardiac Catheterization

Cardiac catheterization and selective cineangiography are not necessary for diagnosis; however, such procedures are necessary during staged Fontan surgery. Prior to bidirectional Glenn (stage II), and Fontan (stage III), catheter evaluation is undertaken to define the pulmonary artery pressure and anatomy, to exclude

a persistent left superior vena cava (because it may divert blood away from the pulmonary arteries) and exclude risk factor for poor outcome. The latter are elevated pulmonary artery pressure (mean pressure, > 18 mm Hg) or resistance (> 4 Wood units/ m^2), distorted or small (McGoan ratio of 1.8 or less) pulmonary arteries, poor left ventricular function (end-diastolic pressure above 12 mm Hg),

Figure 3 Selected video frame from subcostal view of an infant with tricuspid atresia demonstrating right-to-left (R to L) shunt (arrow) across the interatrial communication
Abbreviations: LA, left atrium; RA, right atrium.

significant mitral regurgitation, subaortic obstruction, and severe left ventricular hypertrophy. At the same time, aortopulmonary collaterals should be evaluated by means of selective subclavian artery and descending thoracic aortic angiography. If collateral vessels are present, they should be occluded with coils or devices, as appropriate.

DIFFERENTIAL DIAGNOSES

There are many other cardiac defects that cause cyanosis or congestive heart failure. The differential diagnosis is largely based on evaluation of pulmonary blood flow on a chest roentgenogram.

Decreased Pulmonary Vascular Markings

The most frequently encountered CHDs in this group are tetralogy of Fallot (TOF), pulmonary atresia with intact ventricular septum and complex cyanotic CHD with pulmonary stenosis or atresia. Differential diagnosis of these infants can be made by analysis of the electrocardiogram (ECG) (**Fig. 7**). Patients with tetralogy of Fallot exhibit right axis deviation ($+90$ to $\pm 180^\circ$) in the ECG; right ventricular hypertrophy may also be present. Infants with pulmonary atresia with intact ventricular septum are likely to have an axis of 0 to $+90^\circ$. The R waves in leads V1 and V2 and S waves in leads V5 and V6 (right ventricular voltages) are decreased and left ventricular hypertrophy (LVH) may be seen. Children with TA, on the other hand exhibit LAD (superior vector) 0 to -90° . They may have LVH and decreased right ventricular voltages. The final group with complex pulmonary stenosis includes cyanotic heart defects such as single ventricle, double outlet right ventricle, ventricular inversion and others, all associated with severe pulmonary stenosis or atresia. The axis and ventricular hypertrophy patterns in the ECG vary markedly in this subgroup. Each of the above defects has characteristic echocardiographic features and the diagnosis may be confirmed by echo.

Increased Pulmonary Vascular Markings

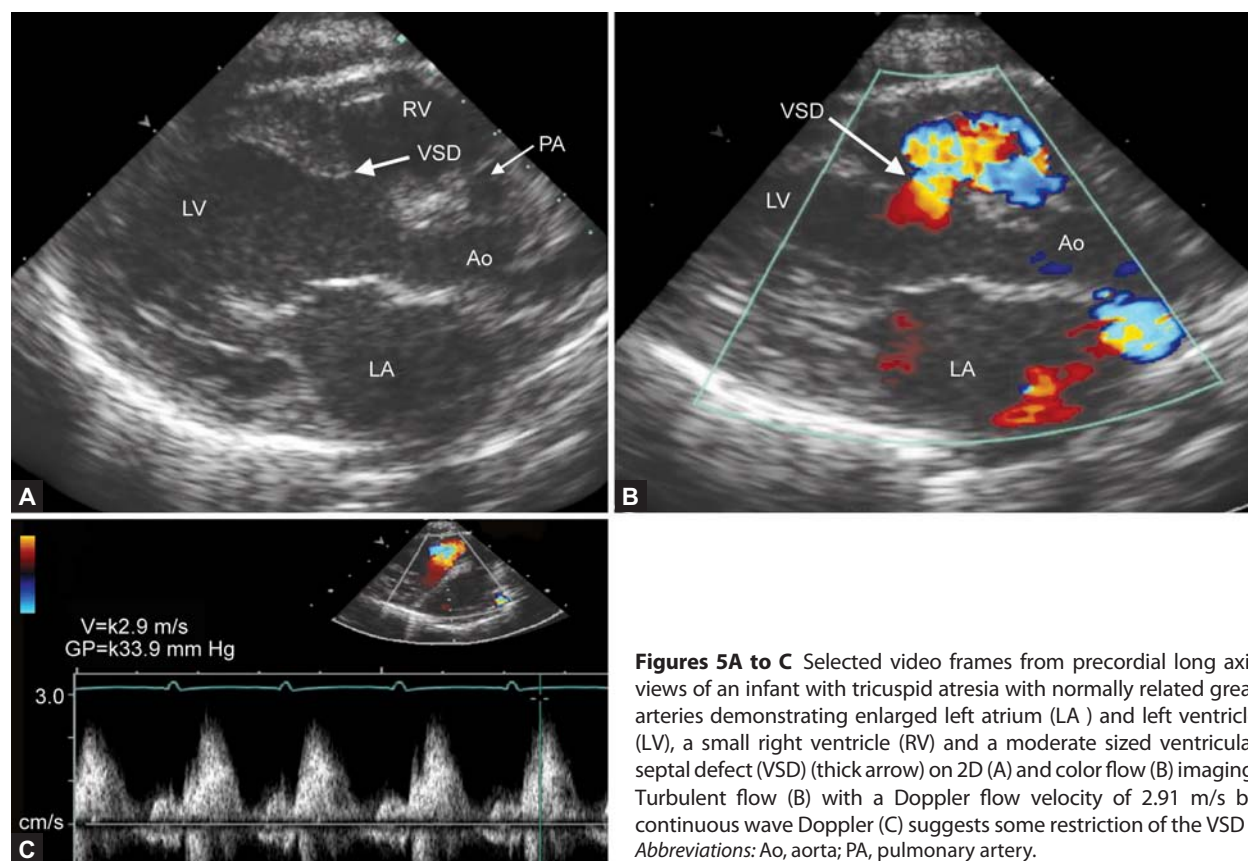

The most frequent defects in this group in the early neonatal period are transposition of the great arteries (TGA), hypoplastic left heart syndrome (HLHS) and coarctation of the aorta syndrome. Patients with multiple left to right shunt lesions manifest more commonly beyond the neonatal period.

Children with TGA typically manifest with severe cyanosis, have minimal distress and have no symptoms of heart failure. Chest X-ray shows mild cardiomegaly with increased pulmonary vascular markings. ECG is either normal or may demonstrate RVH. Blood gases shows severely decreased PO_2 and oxygen saturation. The PO_2 does not get better with 100% O_2 .

Neonates with HLHS show signs of severe congestive heart failure, have minimal cyanosis, but have obvious respiratory distress, hepatomegaly, and decreased pulses in all four extremities.

Figures 4A and B A selected video frame from precordial long axis views of a child with tricuspid atresia and transposition of the great arteries demonstrating left atrium (LA), left ventricle (LV), a very small right ventricle (RV) and a moderate sized ventricular septal defect (VSD). The vessel coming off of the LV is traced in B and shown to bifurcate into left (LPA) and right (RPA) pulmonary arteries confirming that this vessel is main pulmonary artery (MPA)
Abbreviation: Ao, aorta.

Figures 6A and B Selected video frames from suprasternal notch views of the aortic (Ao) arch in 2D (A) and color flow (B) images of a neonate with tricuspid atresia and transposition of the great arteries demonstrating coarctation of the aorta (CoA) and hypoplastic transverse aortic arch (TAA). Abbreviation: DAo, descending aorta.

On chest roentgenogram severe cardiomegaly is present. ECG shows decreased left ventricular forces and RVH. On blood gas analysis, PO_2 and oxygen saturation are only mildly decreased, but may show metabolic acidosis. The PO_2 may improve to some extent

with 100% O_2 , but never above 150 torr. The clinical distinction between TGA, HLHS is rather simple: the main difficulty of infants with TGA is one of cyanosis, whereas the problem of infants with HLHS is one of heart failure with hardly recognizable cyanosis.

Figure 7 This figure illustrates the usefulness of frontal plane mean QRS vector (axis) in helping differential diagnosis of cyanotic heart defects with decreased pulmonary flow. A frontal plane axis between 0° and -90° is suggestive of tricuspid atresia, an axis between 0° and +90° is indicative of pulmonary atresia with intact ventricular septum and an axis between +90° and ±180° is associated with tetralogy of Fallot. The accompanying ECG abnormalities are also displayed in the appropriate quadrant. Cyanotic infants with complex heart defects with associated severe pulmonary stenosis/atresia may fall into any quadrant

Abbreviations: LVH, left ventricular hypertrophy; RV, right ventricle; RVH, right ventricular hypertrophy.

Babies with coarctation of the aorta may have decreased femoral pulses, are not usually cyanotic, and when low, improve with 100% O₂. Children with TA babies have LAD and LVH on the ECG. Echocardiogram is diagnostic for each of these entities.

When the neonate presents late in the neonatal period, the differential diagnosis is multiple left to right shunts and several complex cyanotic congenital heart defects such as double-in-let left ventricle (Single ventricle), double outlet right ventricle along with tricuspid atresia with a large ventricular septal defect, all without pulmonary stenosis. Majority of defects require echocardiography for making a diagnosis.

MANAGEMENT

Fontan procedure, considered a physiologically “corrective” surgery for TA, is usually performed in patients older than 2 years. However, the majority of children with TA present early in life. Consequently, such early presenting infants must get effective palliation to allow them to reach the age when safe corrective surgery can be undertaken.

1. Medical Management at the Time of Presentation

Management steps during the process of identification, transfer to a pediatric cardiology center, initial workup and during and after palliative surgery or procedures entail preservation of neutral thermal environment, normal acid-base balance and normal blood glucose and calcium with appropriate monitoring and correction, as necessary. Unless there is pulmonary parenchymal pathology, no more than 40% oxygen (FiO₂) is necessary.

Prostaglandin Infusion for Ductal Patency

Neonates with low arterial oxygen saturation are likely to have ductus-dependent pulmonary blood flow. Therefore, the

ductus should be kept open by intravenous administration of prostaglandin E₁ (PGE₁), with a starting dose of 0.05 µg/kg/min and gradually reducing it to 0.02 µg/kg/min, provided the desired oxygen tension levels are maintained. Such low doses are helpful in reducing the frequency and severity of some of the drug’s side effects such as apnea and hyperpyrexia.

Those infants presenting with signs of CHF (more common in type II patients) need treatment with routine anticongestive measures. Neonates with severe coarctation of the aorta also need PGE₁ infusion; this time, the ductal dilating effect of PGE₁ improves systemic perfusion.

2. Palliative Treatment of Specific Physiologic Abnormalities

The functional type of hemodynamic abnormality produced by the cardiac anomalies determines the nature of palliative management. These will be grouped into those with decreased pulmonary blood flow, increased pulmonary blood flow, and intracardiac obstruction.

Decreased Pulmonary Blood Flow

Systemic-pulmonary artery shunts are most commonly used in palliating pulmonary oligemia. Modified Blalock-Taussig shunt, with a Gore-Tex graft interposed between the subclavian artery and the ipsilateral pulmonary artery is most commonly utilized at the present time (Fig. 8). Stenting the ductus arteriosus is not currently an initial therapeutic choice.

Rarely, the predominant obstruction may be at the pulmonary valve level, and in such babies, balloon pulmonary valvuloplasty may help increase pulmonary blood flow.

Increased Pulmonary Blood Flow

Infants with mild to moderate increase in pulmonary blood flow without signs of congestive heart failure should be observed and no treatment is necessary. Infants with markedly increased pulmonary blood flow are likely to develop congestive heart failure; most of these babies belong to type IIc and rarely, type Ic.

In type I babies, anticongestive measures such as diuretics (Furosemide), after load reducing agents (Captopril) and inotropes (Digoxin), as appropriate should be promptly started. The natural history studies show that the VSD spontaneously closes and the

Figure 8 A selected cineangiographic frame to demonstrate a modified Blalock-Taussig (MBT) shunt, connecting the subclavian artery to the right pulmonary artery (RPA) with a Gore-Tex graft (MBT) Abbreviation: LPA, left pulmonary artery.

infants with pulmonary plethora will, in time, develop pulmonary oligemia requiring a palliative shunt. Consequently, the previously resorted to pulmonary artery banding procedure is not performed initially in this group of patients. If optimal anticongestive measures do not result in improvement, then pulmonary artery banding using absorbable band should be entertained.

If pulmonary artery banding is not performed, periodic estimation of pulmonary artery pressure should be undertaken in order to prevent pulmonary vascular obstructive disease. Initially, the absorbable polydioxanone band decreases pulmonary artery pressure by restricting the pulmonary blood flow and helps improve symptoms of heart failure. As the VSD spontaneously closes, the pulmonary artery band is resorbed and prevents severe pulmonary oligemia that may be seen with a conventional non-absorbable band.

In type II babies, banding of the pulmonary artery (**Fig. 9**) should be performed once the infant gets stabilized following anticongestive therapy. If coarctation of the aorta is present, adequate relief of the aortic obstruction should be undertaken concurrent with pulmonary artery banding. The importance of initial PGE₁ administration in the control of congestive heart failure has already been mentioned.

Intracardiac Obstruction

Intracardiac obstruction may develop at the patent foramen ovale and/or at the VSD. The development of interatrial obstruction in a few patients at the patent foramen ovale evidenced by a mean atrial pressure difference of 5 mm Hg or more with prominent 'a' waves (15–20 mm Hg) in the right atrium should be relieved by Rashkind balloon atrial septostomy. Interventricular obstruction with spontaneous closure of the VSD causes severe pulmonary oligemia in type I patients and subaortic obstruction in type II patients.

Management in Type I TA

Cyanotic spells, similar to those observed in tetralogy of Fallot resulting from the functional closures occurring in infants with normally related great arteries (type I), are managed the same way as Fallot's tetralogy spells get treated. Pulmonary oligemia following partial or complete anatomic closure of the VSD in type I patients is treated with Blalock-Taussig shunt in young infants and bidirectional Glenn procedure in older infants and children, preparatory to a modified Fontan operation.

Figure 9 A selected cine frame from main pulmonary artery (MPA) cineangiogram in straight lateral view demonstrating constriction of the pulmonary artery (PB) (arrow)
Abbreviations: LPA, left pulmonary artery; RPA, right pulmonary artery.

Management in Type II (TA with Transposition)

Subaortic obstruction due to partial closure of the VSD in these children is relieved by resection of the conal muscular septum, thereby enlarging the VSD or bypassed by performing anastomosis of the proximal stump of the divided pulmonary artery to the ascending aorta at the time of bidirectional Glenn (or Fontan) operation (Damus-Kaye-Stansel procedure).

3. Medical Management after Palliative Operation

In babies with single ventricle physiology (including palliated tricuspid atresia patients), the systemic and pulmonary circulations function in-parallel rather than normal in-series circuits; a delicate balance of the blood flows between the two circulations exists. Intercurrent illnesses that produce dehydration, acidosis, or fever upset the balance between the two circulations and cause a patient to become critically ill. These intercurrent illnesses do cause significant interstage mortality. In addition blockage of the Blalock-Taussig shunt may develop. Consequently, even minor illnesses must be treated aggressively.

Other issues in TA being similar to those seen in other types of cyanotic heart defects must be closely monitored, prevented whenever possible and treated adequately at the earliest: Relative anemia, polycythemia, coagulopathy, cerebrovascular accident or brain abscess and hyperuricemia, gout, and uric acid nephropathy should be prevented by timely palliative or corrective operative therapy. Antibiotic prophylaxis prior to any bacteremia-producing procedures or surgery is indicated, as is routine immunization plus consideration for palivizumab (for prevention of RSV infection in infancy), polyvalent pneumococcal vaccine or influenza vaccine.

4. Corrective Surgery

Successive modifications of the initially performed Fontan and associates' physiologically corrective surgical procedure for tricuspid atresia have tried to minimize the mortality and the earlier postoperative problems and thus maximize the quality of life of survivors. At the present time staged total cavopulmonary diversion (de Leval and his colleagues) is the procedure of choice because of technical simplicity, maintenance of low right atrial and coronary sinus pressure, and reduction in risk of formation of thrombus in the Fontan circuit.

Stage I

At this stage (**Figs 8 and 9**), usually at presentation in the neonatal period, Blalock-Taussig shunt, observation without any surgery or banding of the pulmonary artery is performed depending upon the status of the pulmonary blood flow as detailed above in the section on "Palliative Treatment of Specific Physiologic Abnormalities".

Stage II

In this stage, a bidirectional Glenn procedure (**Fig. 10**) is performed around the age of 6 months. The bidirectional Glenn procedure consists of anastomosing upper end of the divided superior vena cava, end to side, to the superior aspect of the undivided right pulmonary artery, thus diverting the superior vena caval blood into both right and left pulmonary arteries. Atrial septal defect is also enlarged at this time. The hemodynamic advantages associated with the bidirectional Glenn are improved effective pulmonary flow, reduced total pulmonary flow, and less left ventricular volume overloading. If both right and left superior vena cava are present, bilateral bidirectional Glenn shunting should be performed, especially if the bridging innominate vein is absent or small.

Stage III

Stage III consists of diverting the inferior vena caval blood into the pulmonary artery (**Fig. 11**), usually by an extracardiac, non-

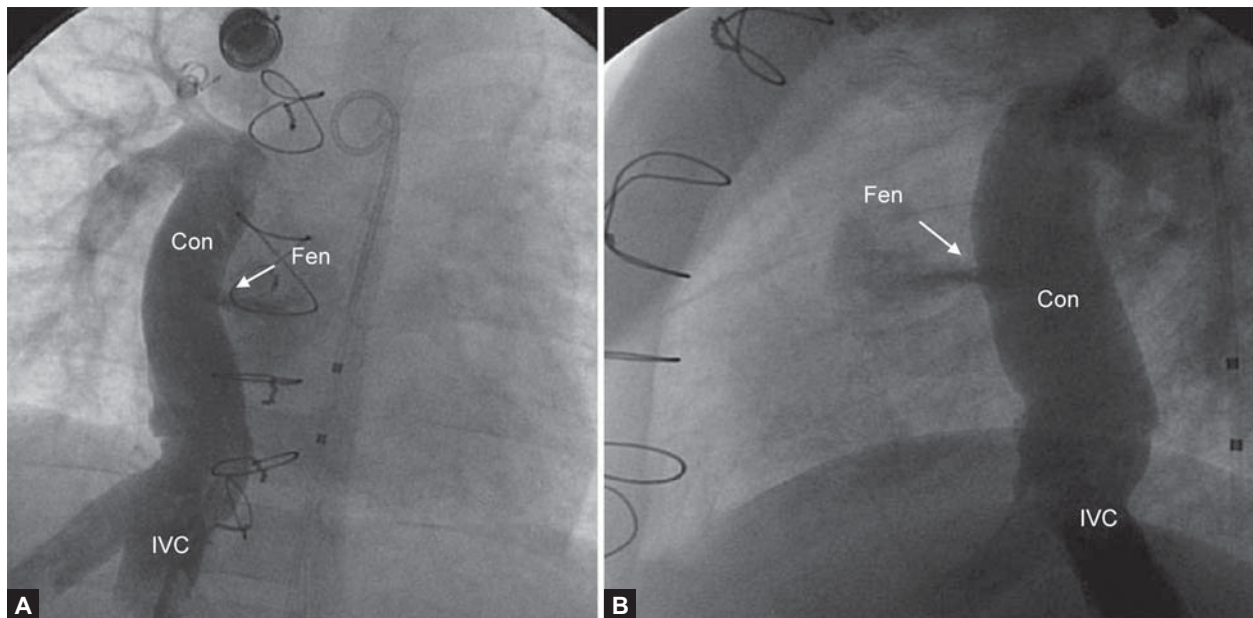

Figure 10 Selected cine frames from superior vena caval (SVC) angiogram in two different children demonstrating the opacification right (RPA) and left (LPA) pulmonary arteries

Figures 11A and B Selected cine frames from inferior vena caval (IVC) angiogram in posteroanterior (A) and straight lateral (B) views demonstrating the conduit (Con) and the fenestration (Fen)

valved conduit (instead of lateral tunnel). Most surgeons leave a fenestration (**Fig. 11**) between the conduit and the right atrium. The procedure is usually performed around the age of 2 years. The fenestration may be closed 6–12 months after Fontan (**Fig. 12**).

Other associated problems such as aortic coarctation, atrial septal obstruction, subaortic obstruction, mitral regurgitation, narrowed pulmonary arteries and others are addressed as and when they are recognized and in association any of the above stages.

5. Follow-up after Corrective Operation

Continued inotropic and diuretic therapy may be needed in some. Afterload reduction with an angiotensin-converting enzyme inhibitor is advocated whenever needed. Routine use of anticoagulants to prevent development of thrombi in the Fontan

circuit, platelet-inhibiting doses of aspirin is preferred instead of Warfarin. This may be changed to clopidogrel in adulthood. Appropriate monitoring and prompt institution of treatment of complications such as arrhythmia, obstructed pulmonary outflow pathways, persistent shunts, and systemic venous congestion including protein-losing enteropathy.

OUTCOMES/PROGNOSTIC FACTORS

The prognosis of neonates with untreated tricuspid atresia is dismal. Early identification, rapid transport to a center equipped to treat complex congenital heart defects, noninvasive echocardiographic diagnosis, availability of PGE1 to keep the ductus patent, and advances in anesthesia and surgical technique have improved the prognosis of tricuspid atresia babies.

Figures 12A and B Selected cine frames from inferior vena caval (IVC) angiograms in posteroanterior view prior to (A) and immediately following (B) Amplatzer device (D) closure of the fenestration (Fen); note complete closure of the fenestration. The right atrial component of the device (D) is only faintly seen

Abbreviation: Con, conduit.

The next mortality used to be in the second decade of life, which is now reduced with a timely physiologically corrective, Fontan operation. The complications seen with the classic Fontan operation (atriopulmonary anastomosis) such as arrhythmia, atrial thrombosis and protein-losing enteropathy appear to have decreased with current surgical strategy of staged, fenestrated cavopulmonary connection.

PREVENTION

Since a multifactorial inheritance hypothesis is offered to explain all other congenital heart defects, including tricuspid atresia, prevention of the fetus to exposure of environmental triggers is likely to be helpful in prevention; however, no specific factors are clearly identified for tricuspid atresia.

IN A NUTSHELL

1. Tricuspid atresia (TA) is the third most common cyanotic congenital heart defect.
2. Tricuspid atresia is classified based on the great artery relationship and the status of the pulmonary outflow tract.
3. Tricuspid atresia infants become symptomatic early and 80% of them present with symptoms within the first month of life.
4. Presence of LAD in ECG in a cyanotic infant is characteristic and virtually diagnostic of TA.
6. Prompt diagnosis and treatment to normalize pulmonary blood flow by PGE₁ administration and Blalock-Taussig for babies with pulmonary oligemia and anticongestive measures and banding of the pulmonary artery for infants with pulmonary plethora are likely to improve prognosis.
7. Staged cavopulmonary anastomosis is the treatment of choice for tricuspid atresia.

Chapter 40.23

Transposition of Great Arteries

R Suresh Kumar, Navaneetha Sasikumar

Transposition of great arteries (TGA) is a condition in which the great arteries arise from the wrong ventricles—aorta from right ventricle (RV) and pulmonary artery (PA) from left ventricle (LV). The term complete TGA refers to the condition in which there is ventriculoarterial discordance (as indicated above) with atrioventricular concordance (right atrium to RV and left atrium to LV) and indicates that the transposition is not physiologically corrected. This may occur in situs solitus or situs inversus. Corrected TGA refers to the state where there is both ventriculoarterial and atrioventricular discordance (RA-LV-PA and LA-RV-Aorta) thereby resulting in physiologically corrected circulation.

EPIDEMIOLOGY

Complete TGA, accounting for 5–7% of all congenital cardiac malformations, is the most common cardiac cause for cyanosis in the newborn. Males are more frequently affected than females, with a reported male: female ratio ranging from 1.5:1 to 3.2:1. Non-cardiac malformations are uncommon and are found only in less than 10% of cases.

ETIOPATHOGENESIS

As with most of the other congenital cardiac malformations, the exact etiology is not known. Though not universally accepted, gestational diabetes mellitus and prenatal exposure to sex hormone therapy have been reported to be risk factors associated with occurrence of TGA.

In complete TGA, the atria are connected to the appropriate ventricles (atrioventricular concordance), but there is inappropriate origin of the great arteries from ventricles (ventriculoarterial discordance). Embryologically, the origin of PA from RV depends on the development of the subpulmonary infundibulum, which pushes the pulmonary valve upwards and anteriorly. In TGA, the infundibulum develops under the aortic valve, pushing it up and anteriorly to connect to the anterior RV. Absence of the subpulmonary infundibulum causes the pulmonary valve to stay posterior and connect to the posterior LV. The most common spatial orientation of the aortic valve is to the right and anterior to the pulmonary valve (D-transposition), though there may be other variations. Coronary arteries originate from the aortic sinuses facing the pulmonary trunk, but the pattern of distribution varies. Understanding of coronary artery anatomy is of extreme importance to the operating surgeon while performing the arterial switch operation.

Nearly 50% of cases of TGA have associated patent foramen ovale or patent ductus arteriosus. Ventricular septal defect (VSD), left ventricular outflow tract (LVOT) obstruction—amounting to pulmonary stenosis and aortic arch anomalies (coarctation of aorta or interrupted aortic arch) are the other common associations.

HEMODYNAMICS

The hemodynamics of complete TGA with intact ventricular septum [with or without an atrial septal defect (ASD)/patent ductus arteriosus (PDA)] differs from complete TGA with a VSD and/or left ventricular outflow tract obstruction. The latter two will be discussed separately.

In contrast to the normal circulation in series, the circulation in hearts with complete TGA with intact ventricular septum is parallel.

There are two closed circuits. In the first circuit, oxygenated blood flows from the lungs to the left heart only to get pumped back into the pulmonary circulation (through the pulmonary artery arising from the left ventricle). In the parallel second circuit, deoxygenated blood from the right heart chambers is pumped into the systemic circulation (through the aorta arising from the right ventricle) and returns back to the right side. Survival is possible only if there is adequate mixing between the two circulations. Adequacy of inter circulatory mixing is dictated by the location and size of communications, further modified by the pressure gradients and vascular resistances in the respective circuits.

The anatomy and physiology of complete TGA does not affect normal fetal growth and development significantly. Hence, the newborn with TGA has normal weight or may be even heavier. Hypoxia sets in soon after birth. During the brief transitional period, the PDA shunts deoxygenated blood from aorta to the pulmonary artery (effective pulmonary blood flow) and the patent foramen ovale (PFO) shunts oxygenated blood to the right side of the heart and ultimately into aorta (effective systemic blood flow). This intercirculatory mixing may at times be enough to prevent severe hypoxemia. In most of the newborns, the ductus begins to close, resulting in severe hypoxemia, just as the oxygen demand is increasing due to increased metabolism. This leads to increased anaerobic metabolism, increased lactate production and severe metabolic acidosis. The ductus provides systemic venous flow into the PA and the left atrial volume overload drives left to right shunt across PFO, thus delivering some oxygenated blood into aorta and improving systemic oxygen saturation. This forms the basis of prostaglandin E1 infusion in newborns with complete TGA.

When a large VSD is present effective mixing between the two circulations results in minimal cyanosis. Instead, these infants develop cardiac failure by 2 to 6 weeks of life. Complete TGA with a large VSD is prone to accelerated development of pulmonary vascular disease. As definitive treatment is not possible with the development of pulmonary vascular obstructive disease, these infants need early and timely diagnosis and corrective surgery.

Left ventricular outflow tract obstruction occurs in 30% of cases with TGA and VSD; the anatomic substrate is usually complex and occurs at multiple levels. When VSD coexists with LVOT obstruction (pulmonary stenosis) in a patient with TGA, hemodynamics depends on the size of the VSD and the severity of the pulmonary stenosis. When VSD is large and LVOT obstruction severe, the pathophysiology and clinical presentation resemble that of tetralogy of Fallot (TOF).

CLINICAL FEATURES

TGA with Intact Ventricular Septum

These neonates present from day one of life with cyanosis. The first sound is normal, and the second heart sound is single, as the posterior pulmonary valve closure is inaudible. Usually there is no murmur. As the ductus closes, these patients present with worsening cyanosis and tachypnea.

Arterial blood gases show severe hypoxemia and metabolic acidosis. Cyanosis in TGA is uniform. However, reverse differential cyanosis with upper limbs more cyanosed than the lower limbs may be seen if complete TGA is associated with coarctation and a PDA shunting from PA to aorta.

TGA with Large Ventricular Septal Defect

Mild cyanosis might be noticed in the early neonatal period, which becomes more prominent during crying. Physical examination during this period is unremarkable. As the pulmonary vascular resistance falls, the neonate develops clinical features of cardiac failure by 2–6 weeks of life—rapid breathing, feeding difficulty

(suck-rest-suck cycle) and excessive sweating. On examination, cyanosis is usually mild. Resting tachycardia and tachypnea are present and there is increased precordial activity. A third heart sound and low-frequency mid-diastolic flow murmur may be heard at the apex. An early systolic murmur may be heard at the left lower sternal border, the murmur is louder and longer, if the VSD is restrictive. Crepitations in the lung fields and tender hepatomegaly may be the other findings in these neonates with cardiac failure.

TGA with Ventricular Septal Defect and Pulmonary Stenosis (TGA, VSD with PS)

The clinical features of these patients are often indistinguishable from those with tetralogy of Fallot, although cyanosis tends to appear earlier and is more severe. If the pulmonary stenosis is severe, the baby presents with severe cyanosis once the ductus closes. If this is not the case, cyanosis gradually increases with passage of time and later hypoxic spells may occur. Squatting for relief of dyspnea might be noted in older children. There are no features of cardiac failure. The second heart sound is single. A harsh, ejection systolic murmur, arising from flow across the left ventricular outflow tract is present. If the ductus arteriosus is patent, a continuous murmur may be heard below the left clavicle.

APPROACH TO DIAGNOSIS

The most common cyanotic congenital heart disease in newborns on day one is complete TGA, the major differential diagnosis being TOF with severe right ventricular outflow tract obstruction. Presence of a murmur and reduced lung vascularity on chest X-ray indicates TOF. When the neonate presents with profound cyanosis around 48–72 hours of life, coinciding with the timing of ductal closure, other conditions with duct dependent pulmonary circulation should be excluded, e.g., critical pulmonary stenosis or pulmonary atresia with intact ventricular septum. When a large VSD is present and the neonate presents with cardiac failure, the clinical picture mimics other CHDs with increased pulmonary blood flow.

DIAGNOSIS

ECG and chest X-ray findings of the three variants described above are summarized in **Table 1**.

Echocardiography

Echocardiography is the investigation of choice to establish the diagnosis of TGA and to guide the management strategy. Systematic segmental approach, using a combination of imaging windows (subcostal, apical, parasternal and suprasternal) helps in demonstrating atrioventricular concordance and ventriculo-arterial discordance which is characteristic of complete TGA (**Fig. 1**). Associated defects like VSD, ASD, PDA, LVOT/arch obstruction must be looked for. The spatial relationship of the aorta

to the pulmonary artery as well as the coronary anatomy can also be clearly delineated on echocardiography (**Fig. 2**).

Fetal echocardiography can identify TGA in utero. In utero diagnosis facilitates delivery in a tertiary care center where prostaglandin E₁ (PGE₁) therapy can be started and further cardiac care can be provided before severe hypoxia and acidosis set in.

Cardiac Catheterization

Currently, cardiac catheterization is indicated only for neonates requiring a balloon atrial septostomy. Similar systolic pressures are noted in RV and aorta, while left ventricular and pulmonary artery pressures are lower. Left atrial mean pressure is higher before balloon atrial septostomy and drops after that. Systemic arterial PO₂ may be as low as 15–20 mm Hg with saturations like 40–50%. Right ventricular angiogram will show aorta arising from the RV. Older children may need catheterization as part of presurgical evaluation especially in those with VSD and PS, or for evaluation of the severity of pulmonary vascular obstructive disease, if present.

MANAGEMENT

It is important to stabilize the critically ill hypoxic neonate before referring for definitive management. This includes attention to common neonatal issues—correction of hypothermia, hypoglycemia, acidosis, hypocalcemia, dehydration and treatment of sepsis, if any. These problems must be attended to, while investigations are being done. Some neonates may require endotracheal intubation and mechanical ventilation.

Prostaglandin E1 Infusion

It has a major role in stabilizing the neonate with TGA and severe hypoxia. The drug is started as an infusion at an average dose of 50 ng/kg/min (range 10–100 ng/kg/min). The SpO₂ improves to at least 70% in most of these neonates who are only a few days old. Using the lowest effective dose helps to minimize tachycardia and to avoid apnea. PGE₁ infusion increases safety of transportation.

Balloon Atrial Septostomy (BAS)

BAS is a temporizing measure to improve systemic oxygen saturation in the severely hypoxic neonate. First performed by Rashkind in 1966, it marked the beginning of interventional pediatric cardiology. This is indicated in the newborn with TGA/intact IVS and inadequate atrial mixing. It may not be required if unless arterial switch operation is planned in the first week. A balloon catheter is introduced across a PFO from the femoral or umbilical vein. It is filled with contrast material and is pulled across the interatrial septum, under fluoroscopic or echocardiographic guidance, tearing the septum and creating an adequate interatrial communication for intercirculatory mixing. BAS results in immediate improvement of SpO₂ to about 70% and may further rise to 80–90%, if it is combined with PGE₁ infusion.

Table 1 ECG and radiological findings in TGA

	<i>Complete TGA with intact ventricular septum</i>	<i>Complete TGA with large VSD</i>	<i>Complete TGA with VSD and left ventricular outflow tract obstruction</i>
ECG	Right axis deviation (RAD) and right ventricular hypertrophy (RVH) Upright T in V1	Biventricular hypertrophy (BVH), RAD LV volume load	RVH, RAD
Chest X-ray	Egg-on-side cardiac shadow with narrow superior mediastinum; Mild cardiomegaly; Increased pulmonary vascular markings	Cardiomegaly with prominent pulmonary vascular marking; Superior mediastinum is narrow	Decreased pulmonary vascular markings; Normal heart size

Figure 1 Subcostal (left) and parasternal long axis views (right) showing the great arteries arising from the “wrong” ventricles

Figure 2 2-D echocardiogram in complete transposition. Parasternal short axis view showing aorta right and anterior to pulmonary artery. Note the coronary arteries arising from the facing sinuses

Arterial Switch Operation (ASO)

It is today the standard of care of infants with complete TGA. Initially performed by Jatene, the surgery involves transection of aorta and PA so as to cross connect their proximal and distal ends, coronary artery translocation to the new aortic root, and pulling the pulmonary arteries anterior to aorta (Le Compte maneuver). The surgery needs to be undertaken in the first month of life as the LV regresses fast and becomes less efficient in pumping against the systemic circulation. Most surgical centers perform this surgery with less than 5% mortality and excellent long-term outcome.

Management of Late Presenters

The infant with TGA presenting after the first month of life presents a unique challenge in the developing world. Careful assessment of left ventricular adequacy is required. Left ventricular posterior wall thickness, sphericity, mass index and

its relation to left ventricular volume all figure prominently in deciding the suitability for arterial switch operation. The infant unsuitable for primary arterial switch operation may undergo pulmonary arterial banding to prepare the left ventricle to cope up with the increased workload, followed by arterial switch operation after a few weeks to few months (2-stage arterial switch). The alternative is a Mustard (Dacron baffle) or Senning (no synthetic material) operation, where pulmonary venous blood is baffled within the atrium to tricuspid valve and systemic venous return to mitral valve so that RV is allowed to be the systemic ventricle. The strategy gives good results for 10–20 years, after which arrhythmias and systemic ventricular dysfunction become major problems.

TGA with VSD

These infants present with heart failure by 4–6 weeks. They have a tendency to develop pulmonary vascular disease after 3 months of age. Arterial switch operation (and VSD closure) must be undertaken before 3 months to prevent this.

TGA with VSD and LVOT Obstruction (Pulmonary Stenosis)

The presentation depends on the severity of LVOT obstruction, which determines the degree of hypoxia. Severe LVOT obstruction warrants a modified Blalock-Taussig shunt for palliation in early infancy. Less hypoxic infants are followed up with plan for definitive correction by 3–5 years. The definitive procedure is Rastelli operation-baffling the left ventricle to aorta by VSD closure and connecting RV to PA with a conduit. With current technology such children require conduit change several times in their life time.

OUTCOME

If left untreated, 30% of infants with TGA and intact interventricular septum die in the first week of life, 50% within the first month, 70% within six months, and 90% within the first year. Given a large VSD or PDA, survival into first or second decade may occur, but pulmonary vascular disease is almost invariable. Infants with TGA with associated VSD and pulmonary stenosis, when optimally balanced, have longer survival as seen in infants with TOF.

Ten year survival rates of 85–90% have been reported for atrial switch surgeries—Mustard/Senning. Although survival into third or fourth decade may be expected, there is increasing morbidity after the first decade from arrhythmias (sinus node dysfunction), systemic ventricular failure, baffle obstructions and leaks.

Following arterial switch operation done in 1982–99, Losay et al. reported early mortality of 9.2% and survival of 88% at 10 and 15 years. Significant supraaortic pulmonary stenosis and/or neoaortic regurgitation was present in 9%, the former being the most common cause for redo surgery. LV function was well preserved and arrhythmias were uncommon. Asymptomatic coronary artery occlusion may be seen in some.

More recent series report mortality below 5%. Long-term neurodevelopmental outcome in these children is a matter of keen interest, as some manifest problems years later. Conduit obstruction, left ventricular outflow tract obstruction, and arrhythmias contribute to late morbidity and mortality.

IN A NUTSHELL

1. TGA is the most common cardiac cause for neonatal cyanosis.
2. Profound hypoxemia, no murmur, increased lung vascularity and egg-on-side cardiac silhouette are clinical clues to the diagnosis of TGA.
3. 2-D echocardiography is the gold standard for diagnosis.
4. Prostaglandin infusion can help in stabilizing a severely hypoxic neonate, before transferring to a tertiary care center.
5. Balloon atrial septostomy (BAS) is performed, if arterial switch operation is not being done immediately. BAS significantly improves SpO₂ and usually allows the baby to stay with the mother.
6. Arterial switch operation, done in the first month of life is the benchmark of present day care in TGA. In good centers this surgery carries less than 5% mortality.
7. Long-term neurodevelopmental outcome needs close monitoring after neonatal arterial switch.
8. In utero diagnosis by fetal echocardiography helps in better planning of neonatal management.

Chapter 40.24

Truncus Arteriosus

Duraisamy Balaguru

Truncus arteriosus (T.Art) is a conotruncal anomaly characterized by a common arterial trunk from which pulmonary artery (PA) originates. T.Art is a distinct entity from aortopulmonary window where the great arteries have a communication between them and there are two separate semilunar valves.

PATHOLOGY AND CLASSIFICATION

Truncus arteriosus is characterized by presence of only one semilunar valve (truncal valve) from which a common arterial trunk originates. The PAs originate from the ascending portion of the common arterial trunk either as main PA which then bifurcates or as separate branch PA and the pattern of origin of PAs is the basis for Collett and Edward's Classification (1949) (**Fig. 1**). Type 4 shown is no longer considered part of T.Art and is reclassified under pulmonary atresia with ventricular septal defect.

Associated Lesions

A typically large and malaligned ventricular septal defect (VSD) is invariably present with rare exceptions. Truncal valve is sometimes quadricuspid (24%). Other lesions include right sided aortic arch (16%), interrupted aortic arch (10%), atrial septal defect (10%), mitral valve hypoplasia (10%), persistent left superior vena cava (6%), additional VSDs (4%), complete atrioventricular septal defect (2%), extracardiac anomalies (10%) and DiGeorge syndrome (33%). When T.Art occurs with right sided aortic arch or interrupted aortic arch, a possible association with DiGeorge syndrome is extremely high (50–84%). Typically, ductus arteriosus is absent in T.Art, except when associated with interrupted aortic arch.

ETIOLOGY

The etiology of T.Art is multifactorial (genetic and environmental). When associated with right aortic arch anomaly, DiGeorge syndrome with chromosomal microdeletion at 22q11.21 is a high possibility. Velocardiofacial syndrome, CATCH22, Shprintzen syndrome and conotruncal anomaly face syndrome are other names associated with this genetic defect. Developmentally, defective migration of cardiogenic neural crest cells that form the conotruncal portion of the heart leads to defective spiral septum

formation, e.g., failure of separation of common arterial trunk into two great arteries.

CLINICAL PRESENTATION

In late neonatal period children with T.Art present with mild, subtle cyanosis that may be missed by even well trained eyes because of increased pulmonary blood flow. They present clinically in the first 3 months with poor and interrupted feeding, respiratory distress, tachypnea, tachycardia, features of heart failure due to fall in the neonatal pulmonary vascular resistance from regression of fetal PA musculature.

If T.Art with interrupted aortic arch is not recognized prior to patent ductus arteriosus (PDA) closure, neonates present when PDA closes in a few days of age with absent femoral pulse, circulatory shock, respiratory distress and metabolic acidosis. Without interrupted aortic arch, presentation depends on presence and degree of PA stenosis.

Physical Examination

As outlined above, physical findings are dependent on the status of pulmonary blood flow. In a typical patient without PA stenosis, there are features of increased pulmonary blood flow with diastolic reversal of flow in the aorta. This leads to a large volume pulse with hyperdynamic precordium. Tachypnea, chest retraction with features of heart failure from increased pulmonary blood flow will be notable similar to cases of a large VSD. When there is PA stenosis, pulmonary blood flow is normal or decreased, there will be cyanosis without signs of respiratory distress. Auscultation reveals normal or loud S_1 . Systolic click from truncal valve abnormalities or dilatation of the common arterial trunk may be present. Single S_2 is noted due to presence of only one semilunar valve. Loud S_2 in the presence of pulmonary hypertension in older infants is expected. There will be a systolic ejection murmur from PA stenosis. This may be high pitched, continuous murmur if there is significant stenosis. Truncal valve regurgitation if present will manifest a high-pitched, early diastolic murmur similar to aortic regurgitation. An apical, low-pitched diastolic rumble (mid-diastolic murmur) of increased flow through a normal mitral valve will reflect increased pulmonary blood flow.

DIFFERENTIAL DIAGNOSIS

For infants with cyanosis, differential diagnosis will include the other cyanotic conditions with increased pulmonary blood flow—transposition of great arteries with ventricular septal defect, double-outlet right ventricle, tricuspid atresia with large VSD, single ventricle without pulmonary stenosis and total anomalous

Figure 1 Collett and Edward classification of truncus arteriosus (1949). Note: Type 4 is no longer considered a type of truncus arteriosus, but is considered a type of pulmonary atresia with ventricular septal defect

pulmonary venous return (TAPVR). Tricuspid atresia will have an ECG with left axis deviation and left ventricular dominance. TAPVR will have right ventricular dominance.

NATURAL HISTORY

The survival of infants born with T.Art without any specific intervention is 30% beyond 3 months and only 12% beyond the first year. The cause of death is heart failure from increased pulmonary blood flow and early development of pulmonary arterial hypertension (PAH). Those who survive beyond 1 year have associated PA stenosis that restricts increased pulmonary blood flow and development of PAH. Nearly, half of these survivors live up to their teen age or beyond. Eventually, Eisenmenger syndrome due to severe PAH sets in making it inoperable.

DIAGNOSIS

Chest X-ray

Cardiomegaly in an infant with increased pulmonary vascular markings (**Fig. 2**) arising from the hilar regions in a slightly higher position is typical. Presence of right sided aortic arch in early infancy with previously described clinical features offers a reasonable clue to the likelihood of presence of T.Art. An infant with T.Art and severe PA stenosis will have normal sized cardiac silhouette and normal or diminished pulmonary vascular markings. Cardiomegaly and pulmonary plethora decrease in older children with the development of PAH.

Electrocardiogram

Electrocardiogram findings are not diagnostic. In newborn, initial ECG may be normal for age. Normal axis with biventricular hypertrophy in a minimally cyanotic infant must entertain this diagnosis. Left ventricular hypertrophy alone may be a later finding. Right arterial enlargement is seen in late infancy and childhood with the development of PAH.

Echocardiogram

Echocardiogram, diagnostic of T.Art, is characterized by presence of only one semilunar valve over-riding a malaligned large outlet VSD. Type of T.Art will be recognized from pattern of origin of PA. Other objectives of performing echocardiogram are to define

Figure 2 Chest X-ray of a 5-day-old newborn with truncus arteriosus. Chest X-ray shows moderate cardiomegaly and bilateral increased pulmonary vascular markings with congestion. This is characteristic but not diagnostic of truncus arteriosus

and detect truncal valve anatomy and function, branch PA size and stenosis, sidedness and patency of aortic arch, and other associated defects. Rarely, cardiac MRI or cardiac catheterization are performed, when echocardiogram cannot define all necessary aspects of the defect, especially when aortic arch or its interruption cannot be clearly defined.

TREATMENT

Initial Medical Management

The modes of clinical presentation determine the initial medical management. When the newborn presents due to associated interrupted aortic arch and closure of ductus arteriosus, management consists of resuscitation and stabilization, along with starting prostaglandin infusion to reopen ductus arteriosus. In neonate or young infant with T.Art, who presents with increased pulmonary blood flow and features of heart failure, diuretics and digoxin should be used in adequate doses along with adequate nutrition with daily calorie intake exceeding 100 calories/kg/day. Hypocalcemia and immunodeficiency related to DiGeorge syndrome will need appropriate medical management.

Surgical Management

Surgical repair of T.Art (**Fig. 3**) consists of closure of VSD using a patch, disconnection of PA from common arterial trunk and repair of this site and placement of a valved, homograft conduit (RV-PA conduit) from right ventricle to the disconnected PA. Truncal valve repair may be needed when regurgitation is severe. Timing of surgery depends on the status of pulmonary blood flow. If the baby is asymptomatic, surgery may be performed at any time from birth to 4-6 weeks. Palliative PA banding is no longer favored due to technical difficulties. After neonatal period, surgical repair is done as soon as the condition is diagnosed. T.Art with interrupted aortic arch always warrants neonatal repair in spite of its associated higher risk.

Figure 3 Surgical repair of truncus arteriosus. Repair consists of VSD patch closure, RV-PA conduit using a valved-homograft and repair of the prior site of origin of main pulmonary artery in type 1 truncus (or branch PA in types 2 and 3)

Abbreviations: VSD, ventricular septal defect; MPA, main pulmonary artery; RV-PA conduit, right ventricle to pulmonary artery conduit.

OUTCOME

Early surgical mortality is 10%. Mortality increases to 30% with additional truncal valve repair and to 60% with interrupted aorta repair. In the long-term, these operated children need repeat surgeries to replace RV-PA conduits as the child grows and possible balloon dilatation or stenting of stenosed PA branch by interventional catheterization. Reported survival at 15 years is 83% in the early survivors of initial surgery.

Follow-up

The objectives of much needed regular follow-up of operated patients are to identify long-term sequelae and progression of residual lesions such as stenosis of RV-PA conduit, regurgitation of truncal valve or conduit valve, and branch PA stenosis. Recoarctation may occur in patient who needed repair of interrupted aortic arch. In a stable patient, yearly follow-up with clinical examination, Chest X-ray, ECG and echocardiogram will suffice.

Unoperated patients may need to be evaluated for reversibility of pulmonary hypertension by cardiac catheterization with pulmonary vasoreactivity testing. However, if the patient is inoperable, palliative medical care is indicated. Follow-up evaluation will include recording pulse oximetry for systemic oxygen saturation, symptomatic management of cyanosis and its consequence, and heart failure secondary to pulmonary hypertension.

Long-term Outcome

Natural history section above provides outcome for unoperated patients. Among operated patients who survive early surgery, 83% survival is noted at 15 years of age. These survivors can be expected to have normal growth and development, barring any intraoperative complications such as stroke and developmental delay from DiGeorge syndrome or other extracardiac anomalies.

Maintenance of good dental hygiene and endocarditis prophylaxis are indicated. Even though, they are restricted from competitive sports active lifestyle with recreational sports is encouraged.

IN A NUTSHELL

1. Truncus arteriosus is almost invariably associated with malalignment of VSD.
2. Associated lesions (PA stenosis and interrupted aortic arch) alter the clinical presentation.
3. Truncus arteriosus with right aortic arch has high association with DiGeorge syndrome.
4. Clinical presentation depends on severity of associated lesions.
5. Medical management is only temporizing measure. Surgery is indicated during infancy.
6. Outcome for isolated T.Arch is better than when associated with truncal valve regurgitation or interrupted aortic arch.

Chapter 40.25

Ebstein Anomaly, Pulmonary Arteriovenous Fistula, Corrected Transposition of Great Arteries

Sunita Maheshwari

EBSTEIN ANOMALY

Ebstein anomaly, seen in 1 per 200,000 livebirths, is an abnormality of the tricuspid valve which can lead to tricuspid regurgitation (TR) and varying degrees of true right ventricular hypoplasia. The functional impairment of the right ventricle (RV) and regurgitation of the tricuspid valve retard forward flow of blood through the right side of the heart. In addition, during contraction of the atrium, the atrialized portion of the RV balloons out, decreasing further the volume of ejected blood. The overall effect on the right atrium is dilation which in turn increases the size of right to left shunting across the atrial septal defect (ASD), if present.

Presentation

Ebstein anomaly can present in the neonate with functional pulmonary atresia due to elevated pulmonary vascular resistance. Signs include respiratory distress, cyanosis and right heart failure, the clue being the presence of massive cardiomegaly (**Fig. 1**) on chest X-ray (CXR) (right atrial enlargement). Alternately, it can be relatively asymptomatic and present later with cyanosis (if there is a concomitant ASD going right to left) or arrhythmias due to the presence of accessory pathways or dyspnea and fatigue due to the TR and cardiomegaly.

The jugular venous pulse (JVP) rarely shows a large V wave despite severe regurgitation of the tricuspid valve because the large right atrium accommodates the increased volume. A widely and persistently split second heart sound and several added sounds are typical. A third and fourth heart sound contribute to the common gallop rhythm. A systolic or diastolic murmur may be audible. Cyanosis and clubbing maybe present.

Figure 1 Massive cardiomegaly seen in neonatal Ebstein anomaly

Diagnosis

The ECG is characteristic with *tall* p waves as well as first degree heart block and low amplitude QRS complexes in the right precordial leads (due to the small true RV). An echocardiogram is diagnostic. The main feature is apical displacement of the septal leaflet of the tricuspid valve from the insertion of the anterior leaflet of the mitral valve (**Fig. 2**) by at least 8 mm/m² body surface area.

While Ebstein anomaly is defined as the congenital displacement of the tricuspid valve towards the apex of the right ventricle, it is often associated with other abnormalities such as an ASD or Wolff-Parkinson-White (WPW) syndrome (pre-excitation).

Treatment

Management varies depending on the clinical scenario of each patient. In neonates in extremis due to functional pulmonary atresia, prostaglandins are lifesaving as they keep the ductus arteriosus open allowing pulmonary blood flow. Simultaneously, oxygen is used to drop the pulmonary vascular resistance which helps forward flow across the pulmonary valve. Complex surgery including tricuspid valve repair or if that is not feasible, closure of the tricuspid valve converting the heart into a single ventricle can be attempted.

Asymptomatic children without significant cyanosis or cardiomegaly can be followed. In the older age group, surgery can be performed for the following indications:

- Limited exercise capacity (NYHA class 3–4)
- Increasing heart size (cardiothoracic ratio greater than 65%).
- Significant cyanosis
- Severe TR with symptoms.

Medical treatment includes diuretics for heart failure. Digoxin should be used with care in the presence of WPW syndrome. Surgical options tend to be highly individualized and include tricuspid valve repair or replacement +/- ASD closure. In situations where the RV is too small, a Glenn shunt (superior vena cava to pulmonary artery connection) may be added to offload the ventricle. If arrhythmias are a presenting complaint, radiofrequency ablation of the accessory pathway will need to be added to the treatment armamentarium.

Individuals with mild Ebstein anomaly, near normal heart size, and no arrhythmias can participate in all sports. Children with severe Ebstein anomaly are at risk for sudden cardiac death and are precluded from sports unless the anomaly has been optimally surgically repaired, the heart size is nearly normal, and no history of arrhythmias exists.

Figure 2 Ebstein anomaly of the tricuspid valve

PULMONARY ARTERIOVENOUS FISTULA

Pulmonary arteriovenous fistula (AVF) is an abnormal connection between an artery and vein in the lungs. Physiologically, the deoxygenated blood from the pulmonary arteries bypasses the capillaries (where oxygenation normally takes place) and directly enters the pulmonary veins and left atrium. So blue blood re-enters the systemic circulation causing cyanosis.

Most commonly pulmonary AVF occur in patients with Osler-Weber-Rendu disease, now commonly called hereditary hemorrhagic telangiectasia (HHT). These patients often have abnormal blood vessels in many parts of the body, including the lung. The 80–90% of patients with pulmonary arteriovenous malformations (AVMs) have HHT. Pulmonary arteriovenous (AV) fistulae can also be seen after certain congenital heart surgeries due to lack of the so called hepatic factor reaching the lungs (e.g., Kawashima, nonpulsatile Glenn). Additionally they can be seen in patients with liver cirrhosis for the same reason.

Presentation

Pulmonary arteriovenous malformations (PAVMs) are classified as *simple* or *complex*. The simple type has a single segmental artery feeding the malformation. Complex malformations have multiple segmental feeding arteries. There is a rare, diffuse form of the disease characterized by hundreds of malformations. Classifying the lesions is helpful in planning treatment, in determining which lesions can be embolized and what form of therapy is most appropriate.

The classical clinical findings are cyanosis, polycythemia, clubbing of the digits, and murmurs over the lung fields in the absence of cardiac disease. While rare, this diagnosis should come to mind in a patient presenting with cyanosis but a structurally normal heart on examination and on echocardiography.

Diagnosis

They may not be visible on a CXR or in 50% they can potentially be spotted on a CXR as well defined rounded or lobulated opacities. When a patient has cyanosis but no known lung or heart or liver disease, one must rule out PAVM via a contrast echocardiogram. A contrast echo is done by a cardiologist wherein agitated saline is injected through a vein while an echo is being performed. Normally, the microbubbles in the saline are absorbed by the capillary system in the lung so after being seen in the right heart only very few are seen in the left heart. However, in PAVM's they pass straight through to the pulmonary veins and left atrium. Therefore on echo, on injecting agitated saline into the arm veins, contrast bubbles noted to enter into the left atrium within 2–3 cardiac cycles raise the suspicion of pulmonary AVF.

Once this diagnosis is suspected, the next step is to do a cardiac catheterization or ideally, a multislice CT or an MRI angiogram to assess the nature, quantity and size of these pulmonary AV fistulae.

Treatment

Untreated, patients can develop worsening cyanosis and polycythemia and they remain at risk for right to left emboli and bleeding into the lung. Shunting of micro emboli bypasses the filtration function of the lungs and may result in development of transient ischemic attacks, a cerebrovascular accident, or a brain abscess. Most deaths attributable to PAVM are caused by stroke, cerebral abscess, hemoptysis, or hemothorax. Therefore treatment is needed. The problem is that treatment can be fairly problematic and needs to be individualized depending on the type and size.

In a simple pulmonary AVM with one large feeding vessel, the feeding artery can be closed in the catheterization laboratory by introducing some variety of vascular plug to occlude it (several types available—coils, plugs, detachable balloons, etc.). In complex malformations, surgical excision has resulted in cure of the disease with disappearance of cyanosis and clubbing when the lesion or lesions are localized to one or two segments of a lung. Diffuse lesions throughout the lungs are difficult to treat with endovascular techniques and are sometimes referred for lung transplant.

CORRECTED TRANSPOSITION OF THE GREAT ARTERIES (c-TGA/L-TGA)

Corrected transposition of the great arteries is one of those controversial cardiac anomalies—its name is not quite accurate and its management remains confusing. Essentially the ventricles are inverted. So although right atrial blood reaches the pulmonary artery, it does so via the left ventricle and pulmonary venous blood reaches the aorta via the RV. In isolated c-TGA therefore, patients are pink and essentially asymptomatic until the RV, which is not used to supporting the aorta, starts to fail.

Presentation

Most patients (90%) with c-TGA have associated anomalies such as a ventricular septal defect (VSD) (80%), pulmonary stenosis (PS) (40%), Ebstein anomaly of the tricuspid valve (10%) or complete heart block (2% chance of developing this per year). In addition to TR and/or right heart dysfunction, it is these associated lesions that can give rise to early symptoms, e.g., heart failure (VSD), exertional dyspnea (PS), cyanosis (VSD, PS), fatigue (heart block), etc.

Diagnosis

The clinical clue to the presence of c-TGA can be found on ECG which demonstrates q waves in lead V1 and absence of q waves in the left precordial leads (**Fig. 3**) and on CXR where the aorta can be noted to be prominent on the left side (L-posed aorta). Echocardiography is diagnostic and morphologically defines the ventricles, the presence or absence of VSD, PS, TR and RV dysfunction. Cardiac catheterization may be needed in selected cases to define the pulmonary artery or other anatomy before surgical intervention.

Treatment

Management is highly individualized depending on the permutation and combination of various symptoms and associated lesions. For instance, at one end of the spectrum, isolated c-TGA with normal functioning RV just needs annual follow-up with an ECG and echo while at the other end, patients with c-TGA VSD PS with cyanosis will need to undergo a complex double switch operation (atrial switch with Rastelli). Similarly patients with c-TGA and a VSD can either undergo a classical repair with VSD closure which leaves the RV as the systemic ventricle or a double switch operation along with the VSD closure which converts the RV into the pulmonary ventricle. Once the RV is made a low pressure chamber again, outcome is theoretically better as RV failure is unlikely to occur. However, the double switch operation is itself high-risk with significant mortality. So, risks versus benefits need to be weighed in each individual case and discussed as a group and with the family before a decision is taken.

Figure 3 ECG in c-TGA demonstrating lack of q waves in leads V5 and V6

IN A NUTSHELL

1. *Ebstein anomaly*: Consider this diagnosis in a neonate with cyanosis, heart failure and massive cardiomegaly on CXR. Echocardiography is diagnostic. Treatment varies from nonintervention in asymptomatic older patients to varied surgeries in sick or cyanotic ones.
2. *Pulmonary AV fistulae*: Consider this diagnosis in a patient presenting with cyanosis but a structurally normal heart on examination and on echocardiography. Contrast echocardiography via a venous line will demonstrate microbubbles entering the left atrium rapidly.
3. *Corrected transposition of the great arteries*: This lesion is commonly detected due to its associations such as heart block, VSD's or pulmonary stenosis. Isolated, it generally needs no treatment. Its associated lesions dictate a complex treatment plan.

Chapter 40.26

Admixture Lesions

Neeraj Awasthy, S Radhakrishnan

Congenital cyanotic heart disease (CCHD) with admixture physiology are defects in which deoxygenated systemic venous (SV) blood returning from the tissues mixes with the fully oxygenated pulmonary venous blood from the lungs in a common receiving chamber. These patients classically present as cyanosis with increased pulmonary blood flow.

CLASSIFICATION

Fully oxygenated pulmonary venous blood mixes with the deoxygenated SV blood resulting in a saturation somewhere in between that of pulmonary venous and SV blood oxygen saturation due to abnormal connections. When mixing is complete, the resultant oxygen saturation will depend on the relative contribution of the amount, of blood from each circulation. We would like to classify the admixture lesions into two further subsets: (1) Admixture lesion with complete mixing, (2) Admixture lesion with incomplete mixing.

Admixture Lesions with Complete Mixing

The effective saturation of admixed blood will be directly related to the amount of oxygenated blood from the lung (pulmonary blood flow) in the presence of normal cardiac output. Thus, the systemic arterial saturation will reflect the amount of pulmonary blood flow. In true sense this subset represents the *admixture physiology*.

Admixture Lesions with Incomplete Mixing

Incomplete mixing can arise on account of: (A) Restrictive communications between the deoxygenated and the oxygenated blood, e.g., transposition of great vessels (TGA) with intact septum, and restrictive interatrial communication, (B) Selective streaming of the deoxygenated and oxygenated blood as in double outlet right

ventricle (DORV) with subpulmonary ventricular septal defect (VSD) and no pulmonary stenosis, univentricular physiology without pulmonary stenosis. In true sense, this subset represents the *transposition physiology*.

Level of Mixing

Mixing at Pretricuspid Level

Venous level Total anomalous pulmonary or SV connection/drainage—supracardiac or intracardiac.

Atrial level Cardiac or coronary sinus type total anomalous pulmonary venous connection (TAPVC); single ventricle with atresia of one of the atrioventricular valves (tricuspid atresia, mitral atresia) without pulmonary stenosis.

Mixing at Post-tricuspid Level

Ventricular level DORV without pulmonary stenosis double outlet LV without pulmonary stenosis, single ventricle physiology (double inlet ventricle) without pulmonary stenosis.

Arterial level Persistent truncus arteriosus.

PHYSIOLOGY OF ADMIXTURE LESIONS

Complete Mixing

Arteriovenous oxygen difference will be about 25% in the basal state, for a normal cardiac index. In admixture lesions, the aortic saturation and the pulmonary artery (PA) saturation will be identical. If the aortic saturation is 85%, PA saturation can be assumed as 85% and pulmonary vein (PV) saturation as 100%. If we assume normal cardiac index, then the arteriovenous oxygen difference will be approximately 25%, that is, the SV saturation will be around 60%. $QP/QS = (AO \text{ saturation} - SV \text{ saturation}) / (PV \text{ saturation} - PA \text{ saturation}) = (85 - 60) / (100 - 85) = 25/15 = 1.67:1$ (Figs 1A and B).

Inherent Errors in Calculations

Let us assume a case of TAPVC If the superior vena cava (SVC) saturation in the above example is 70%, indicating a lesser arteriovenous oxygen difference and also reflecting a higher systemic

Figures 1A and B Schematic diagrams showing the hemodynamics. (A) Showing the schematic diagram of normal heart. (B) Schematic diagram in a case of TAPVC showing the drainage of PVs to right sided atrium with large interatrial communication. If we assume normal cardiac index, then the arteriovenous oxygen difference will be approximately 25%, that is, the SV saturation will be around 60%. $QP/QS = (AO \text{ saturation} - \text{systemic venous saturation}) / (PV \text{ saturation} - PA \text{ saturation}) = (85 - 60) / (100 - 85) = 25/15 = 1.67:1$

Abbreviations: RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; IVC, inferior vena cava; SVC, superior vena cava; Ao, aorta; PA, pulmonary artery; RVOT, right ventricular outflow tract; LVOT, left ventricular outflow tract.

flow. The $Q_p/Q_s = (85-70)/100-85 = 15/15 = 1$. The aortic saturation in this case will still be 85%. The above mathematical example shows that the Q_p gets reduced by increased systemic saturations, thus there is more systemic flow than across the pulmonary vascular bed. But what is practical is that pulmonary venous blood gets directed to a common chamber, drains to right atrium, right ventricle (RV), PA and low resistance pulmonary vascular bed and thus chest X-ray shows pulmonary plethora. In no way is the pulmonary blood flow compromised and it is in fact higher than the basal state.

Let us look at the mathematical calculation example keenly The oxygen is used as an indicator for all the above calculations. The uptake of the oxygen across the bed (be it pulmonary or systemic vascular bed) decides the oxygen saturation across the bed (and this is assumed to be constant).

Let us discuss about Q_p The saturation in PA reflects a saturation of the mixing chamber (atrium) and the pulmonary venous saturation can never exceed 100, so although Q_p will increase because of dissolved oxygen, the ratio would never increase. Rather high Q_s because of high SV saturation will show falsely lower ratios.

Thus there is an inherent error in calculations of Q_p/Q_s ratios (in the absence of looking at dissolved oxygen, which the ratios do not look at) for the admixture lesions. But still the calculations do guide to important observations.

Incomplete Mixing

In classical admixture lesions there is complete mixing in a common chamber and when this is not the case, this can result in two scenarios.

Streaming Phenomenon (Fig. 2)

- When the pulmonary venous return preferentially streams into the aorta (AO) it results in higher oxygen saturation in the AO than the PA (favorable streaming) (**Fig. 2A**)
- When the pulmonary venous return streams into the PA, this results in higher oxygen saturation in PA than AO (unfavorable streaming) (**Fig. 2B**)

Figures 2A and B (A) Schematic diagram of the heart with in a case of admixture lesion (DORV with VSD: subaortic), with streaming of the LV blood to the aorta and the right ventricular blood to the pulmonary circuit (favorable streaming). (B) DORV with subpulmonary VSD, with streaming of the LV blood to the pulmonary artery and systemic blood to aorta (unfavorable streaming)

Abbreviations: DORV, double outlet right ventricle; RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; IVC, inferior vena cava; SVC, superior vena cava; RVOT, right ventricular outflow tract; LVOT, left ventricular outflow tract; VSD, ventricular septal defect.

- With identical pulmonary blood flow, streaming can considerably effect the systemic arterial oxygen saturation based on streaming in the common mixing chamber
- Systemic oxygen saturation is thus influenced both by the total pulmonary blood flow and the type and degree of streaming in the mixing chamber.

Restrictive Communication of the Mixing Chamber (Fig. 3)

The restrictive communication allows for the streaming effect. This is particularly true in pretricuspid admixture lesions. In normal physiology the inferior vena cava (IVC) blood gets directed to the interatrial communication, while the SVC blood gets directed to tricuspid valve. In the presence of restrictive interatrial communication in supracardiac TAPVC will result in more desaturated blood streamed to pulmonary artery, while infradiaphragmatic TAPVC will result in saturated blood to the left side. Similarly the absence of mixing in TGA at interatrial level will lead to the unfavorable streaming.

TOTAL ANOMALOUS PULMONARY VENOUS CONNECTION/DRAINAGE (TAPVC/TAPVD)

Total anomalous pulmonary venous connection (TAPVC) represents abnormal drainage of the pulmonary blood flow to the systemic circuit. Here in PVs forms a pulmonary venous confluence (PVC) and drain to the systemic vein. TAPVC can be divided into:

- *Supracardiac type:* Pulmonary venous confluence to innominate vein or azygous vein
- *Cardiac type:* PVC to the coronary sinus
- *Infracardiac type:* PVC to the IVC. More than one type may coexist in a patient.

Physiology

Right atrium is the mixing chamber irrespective of the site of drainage of TAPVC. The right atrium, RV, pulmonary artery, left atrium, left ventricle (LV), and aortic oxygen saturations are identical. Systemic saturation indirectly reflects the blood flow

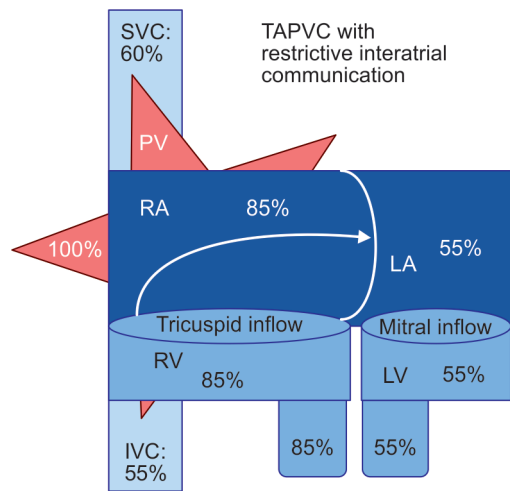

Figure 3 Schematic diagram of the heart with restrictive interatrial communication in a case of admixture lesion (TAPVC), with bulging of the interatrial septum to the left. IVC blood gets directed to the restricted PFO, the only cardiac output and hence the systemic flow is restricted

Abbreviations: RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; IVC, inferior vena cava; SVC, superior vena cava.

across pulmonary vascular bed hence low systemic saturation suggests decreased pulmonary blood flow because of pulmonary vascular disease, while good aortic saturations indicate good pulmonary blood flow.

Streaming in Total Anomalous Pulmonary Venous Connection

Superior vena cava and coronary sinus blood is directed to the tricuspid valve (TV) and IVC blood to the atrial septum hence to the left atrium. Hence supracardiac TAPVC draining into SVC or to coronary sinus streams selectively to the TV, RV, and into PA (unfavorable streaming) and infradiaphragmatic TAPVC draining to IVC selectively streams across the atrial septal defect (ASD) (favorable streaming). Streaming phenomenon results in dissimilar saturation in AO and PA. Causes of low arterial oxygen saturation in TAPVC include: reduced pulmonary blood flow due to pulmonary vascular disease; pulmonary venous desaturation due to pulmonary venous hypertension (PVH) because of obstruction to the channel, site of drainage with or without individual PV obstruction; PVH and unfavorable streaming.

Patients with infradiaphragmatic obstructed TAPVC can maintain fair systemic saturation despite being moribund due to PVH and pulmonary edema due to obstruction in pathway of pulmonary venous blood commonly associated with intra-diaphragmatic TAPVC (unfavorable anatomy) because of favorable streaming.

Associated Lesions and Interventions

Associated pulmonary venous stenosis may decrease the flow across the pulmonary vascular bed; hence coexisting pulmonary venous stenosis may get masked. Alternatively opening of the ductus by prostaglandin may lead to pulmonary edema in this setting.

Clinical Features

Clinical presentation and the age of presentation of TAPVC depends upon the presence and absence of obstruction. *Obstructive TAPVC* presents early with respiratory distress, severe pulmonary venous and arterial hypertension and need to be operated urgently. In an infant of *TAPVC without obstruction* where there is classical

example of admixture physiology on account of good mixing generally occurs at the atrial level, the cyanosis may be subtle. One has to keenly observe for the presence of same. Clinical features resemble that of ASD with left to right shunt. There is wide and fixed splitting of the second heart sound. As there is increased flow across the tricuspid valve a mid diastolic murmur across the tricuspid valve is heard. Because of increased pulmonary blood flow ejection systolic murmur across the pulmonary valve is heard. If any patient with the findings of ASD has cyanosis, the first bedside diagnosis should be TAPVC. Also one may hear the flow through the confluence, e.g., venous hum in the neck or second right intercostal space in case of supracardiac TAPVC.

Investigations

Electrocardiography

Right ventricular hypertrophy (RVH) of the volume overload type (i.e., rsR' in V1) and occasional right atrial hypertrophy (RAH) are present.

Chest X-ray

Cardiomegaly with dilated RA and RV is present with increased pulmonary vascular markings (**Figs 4 and 5**). In supracardiac type the dilated vertical vein, innominate vein and SVC may give classical *Snowman* sign or figure-of-8 configuration. This is rarely seen before 4 months of age. In obstructed TAPVC, the heart size is normal or slightly enlarged. There are features of pulmonary edema (i.e., diffuse reticular pattern and Kerley's B lines). These findings may be mimic pneumonia or hyaline membrane disease of the newborn.

Echocardiography

Echocardiography (**Fig. 6**) is generally diagnostic in most of the patients rarely, CT angiogram may be required to delineate the individual veins.

Management

Medical Management

Intensive anticongestive measures with digitalis and diuretics should be provided for infants without pulmonary venous obstruction. Metabolic acidosis should be corrected, if present.

Figure 4 Chest X-ray frontal view showing characteristic *Snowman* appearance or *Figure of 8* in patient with supracardiac TAPVC draining into left innominate vein through vertical vein. Left upper heart border is formed by ascending vertical vein, superior border by dilated innominate vein and right upper border by dilated SVC

Figure 5 Chest X-ray in obstructed TAPVC in an infant. There is diffuse bilateral pulmonary venous congestion because of pulmonary venous obstruction

Infants with severe pulmonary edema (resulting from the infracardiac type and from other types with obstruction) should be intubated and receive ventilator support with oxygen and positive end-expiratory pressure, if necessary, before cardiac catheterization and surgery. In some patients with pulmonary hypertension, prostaglandin E1 (PGE 1) can increase systemic flow by keeping the ductus open. In the infracardiac type, PGE 1 may be helpful in maintaining the ductus venosus open. If the size of the interatrial communication appears small and immediate surgery is not indicated, balloon atrial septostomy or blade atrial septostomy may be performed to enlarge the communication.

Surgery

Corrective surgery in the form of pulmonary venous rerouting is necessary for all patients with this condition. Obstructed TAPVC should be operated on soon after diagnosis. Nonobstructed TAPVC is usually operated on between 4 and 6 months.

TOTAL ANOMALOUS SYSTEMIC VENOUS DRAINAGE

Clinical features of TASVD will resemble essentially that of TAPVC. There is a strong association of the anomaly with left isomerism with associated features: such as symmetrical *midline* liver (on palpation or X-ray films), discordant cardiac apex and stomach bubble (on chest X-ray films), biliary atresia in a neonate with congenital heart defects, and symmetrical main stem bronchi on chest X-rays. Almost 70% of the hearts have ectopic atrial rhythm with a superiorly oriented P axis (-30° to -90°). With the presence of endocardial cushion defect, a superior QRS axis may be present.

DOUBLE OUTLET VENTRICLE

Double outlet right (Fig. 7) or left ventricle (DORV/DOLV) with subpulmonary VSD and no pulmonary stenosis presents with congestive heart failure (CHF) and cyanosis in infancy. As such these lesions can be kept in differential diagnosis of patients with cyanosis and increased pulmonary blood flow. DORV can have subaortic VSD or subpulmonic VSD. In this admixture lesion mixing chamber is RV but often complete mixing does not occur and thus RV acts as a conduit with LV pumping through it to the great vessels and little opportunity to effect complete mixing in RV. As the flow in RV is essentially in systole with both ventricles contacting, thus incomplete mixing secondary to streaming is commonly seen in DORV with following implications:

- In DORV with subaortic VSD there is favorable streaming with saturated LV blood enters the AO and RV blood enters the PA, this results in saturation significantly higher than PA. Thus DORV with subaortic VSD presents like a large left to right shunt VSD, as the desaturation is mild and cyanosis may not be clinically apparent (Fig. 2A).
- In VSD with subpulmonic location there is unfavorable streaming with PA saturation more than the AO. This subgroup presents clinically as transposition of great arteries with VSD, with significant systemic desaturation (cyanosis) despite increased pulmonary blood flow (Fig. 2B).
- Thus, in DORV the systemic saturation may not accurately reflect the pulmonary blood flow and systemic desaturation is decided by streaming and associated anomalies.

Figure 6 Echocardiogram with color compare in subcostal coronal view showing the drainage of the pulmonary venous blood to the right atrium with dilated right atrium and right ventricle because of malaligned interatrial septum
Abbreviations: RA, right atrium; LA, left atrium; RV, right ventricle; LV, left ventricle; PV, pulmonary valve.

Figure 7 2D echocardiogram in apical 4-chamber view with anterior tilt showing both the great arteries: aorta and pulmonary artery arising from right ventricle in a child with DORV
Abbreviations: PA, pulmonary artery; Ao, aorta; LV, left ventricle; RV, right ventricle; DORV, double outlet right ventricle.

Clinical Features

Clinical features in a case of DORV reflect the location of the VSD in relation to the great arteries; and the relationship of the great arteries. The presence of cyanosis in these lesions is adjudged by two physiological parameters discussed above: the streaming and the amount of pulmonary blood flow.

Subaortic Ventricular Septal Defect without Pulmonary Stenosis

Pulmonary blood flow (PBF) is increased and CHF may result. Therefore, clinical pictures resembles those of a large VSD with pulmonary hypertension and CHF. The child may have growth retardation, tachypnea, hyperactive precordium, a loud S_2 , and a VSD-type (holosystolic or early systolic) murmur. An S_3 and apical diastolic rumble may be audible. ECG may reveal superior QRS axis (i.e., -30° to -170°). RVH or biventricular hypertrophy (BVH), as well as left atrial hypertrophy (LAH), is common. Occasionally, first degree AV block is present. Chest X-ray images show cardiomegaly with increased pulmonary PA segment.

Subpulmonary Ventricular Septal Defect (Taussig-Bing Syndrome)

Clinical pictures in this setting resembles those of TGA. Combination of cyanosis with CHF (TGA physiology), may be because of the selective streaming of the VSD to the pulmonary vascular bed and the SV flow to the systemic arterial circulation. This group present the earliest. Growth retardation and severe cyanosis with or without clubbing are common findings. The S_2 is loud, and a grade 2–3/6 systolic murmur is audible at the upper left sternal border. An ejection click and an occasional PR murmur (as a result of pulmonary hypertension) may be audible. The ECG shows right axis deviation (RAD), RAH, and RVH. Chest X-ray shows cardiomegaly with increased pulmonary vascular markings and a prominent PA segment.

Doubly Committed or Noncommitted Ventricular Septal Defect

Cyanosis of a mild degree is present and the PBF increases.

In general, in a case of CHF with cyanosis presence of extreme RAD on electrocardiogram and presence of narrow pedicle on chest X-ray (pointing to malposed vessels) may be present in some cases and when present are important clinical clue to the diagnosis of DORV with malposed vessels.

Management

The plan of management is essentially surgical and is decided by considering the location of the VSD in relation to great arteries.

SINGLE VENTRICLE

Admixture physiology in single ventricle (**Fig. 8**) may be discussed as below.

Pretricuspid Admixture Lesions

These patients include mitral atresia and tricuspid atresia without pulmonary stenosis. In these setting atria forms the mixing chamber with fairly good mixing as seen in admixture physiology. The manifestations depend upon the degree of pulmonary blood flow.

Post-tricuspid Admixture Lesions

- In single-ventricle physiology both favorable and unfavorable streaming is often seen and does not necessarily depend on the ventricular morphology or the great vessel relation.
- Patients with double inlet left ventricle (DILV) with aorta arising from the left-sided and anterior rudimentary RV outflow chamber (inverted) have SV blood preferentially directed into the PA and pulmonary venous blood to the aorta (preferential streaming).
- Patients with aorta from a right-sided and anterior rudimentary RV outflow chamber (noninverted) may have *unfavorable* streaming.
- These single ventricles have a mixing chamber as the ventricles.
- In this setting the arterial oxygen saturation will reflect pulmonary blood flow.

Figure 8 LV angiogram in LAO cranial view in a case of single ventricle with atretic left component showing the atretic left component marked by arrow

Clinical Manifestations

Cyanosis may be present from birth, depending upon the pulmonary blood flow.

With *increased PBF*, physical findings resemble those of VSD or may be transposition of great vessels: mild cyanosis and CHF with growth retardation; single or narrowly split S_2 with a loud P_2 . A grade 3–4/6 long systolic murmur is audible along the left sternal border. An S_3 or apical diastolic rumble may be present. In case of pulmonary hypertension diastolic murmur of PR may be present along the upper left sternal border.

Physical findings in *single ventricle with decreased PBF* resemble tetralogy of Fallot (TOF). Moderate to severe cyanosis is present. CHF is not present. Clubbing may be seen in older infants and children. The S_2 is loud and single. A grade 2–4/6 ejection systolic murmur may be heard at the upper right or left sternal border.

ECG

An unusual ventricular hypertrophy pattern with similar QRS complexes (monomorphic) across most or all precordial leads is common (e.g., RS, rS, QR pattern). Abnormalities in septal depolarization represented by abnormal Q waves: Q waves in the right precordial leads, no Q waves in any precordial leads, or Q waves in both the right and left precordial leads. Either first- or second-degree AV block may be present. Arrhythmias are not infrequent (e.g., SVT, wandering pacemaker).

TRUNCUS ARTERIOSUS

Persistent truncus arteriosus (PTA) is defined as common arterial trunk arising from base of heart, gives origin to aorta, pulmonary arteries, and coronaries (**Fig. 9**). VSD with truncus is usually large.

Figure 9 Parasternal long axis views with anterior tilt in a case of truncus arteriosus showing large outlet ventricular septal defect (*), over-riding common trunk. The main pulmonary artery arises posteriorly (arrow)
Abbreviations: Ao, aorta; TR, truncus; LV, left ventricle; RV, right ventricle.

It results from absent or deficient outlet septum, perimembranous part of septum is usually intact with truncus arteriosus, in 25% of cases defect may extend to membranous area. Rarely the VSD may be restrictive or even absent. This condition is described in detail in Section 40.24.

IN A NUTSHELL

1. Admixture physiology are defects in which deoxygenated SV blood mixes with the fully oxygenated pulmonary venous blood from the lungs in a common receiving chamber. These patients classically present as cyanosis with increased pulmonary blood flow.
2. The mixing can be complete or incomplete; and can occur either at pretricuspid or post-tricuspid levels. Clinical features will vary accordingly.
3. TAPVC is the most common admixture lesion representing abnormal drainage of the pulmonary blood flow to the systemic circuit. Here in PVs forms a pulmonary venous confluence (PVC) and drain to the systemic vein. TAPVC can be divided into: *Supracardiac type*: Pulmonary venous confluence to innominate vein or azygos vein; *Cardiac type*: PVC to the coronary sinus; and *infracardiac type*: PVC to the IVC. More than one type may coexist in a patient.
4. Double outlet ventricle, single ventricle, and truncus arteriosus are the other common admixture lesions described in this chapter.
5. Admixture lesions are fairly important subgroup and their hemodynamic gets governed by pulmonary blood flow in classical lesions and also gets influenced by streaming, degree of obstruction to mixing and associated lesions.
6. Operability needs to be individualized to each respective admixture lesion. In general CHF, cardiomegaly and arterial saturation 85% or more favor operability.

Chapter 40.27

Hypoplastic Left Heart Syndrome

Joseph John Vettukattil

Hypoplastic left heart syndrome (HLHS) refers to a spectrum of heart defects where hypoplasia (underdevelopment) of the left heart structures, e.g., left atria, left ventricle, ascending aorta or the aortic arch occur secondary to either stenosed, atretic or hypoplastic morphological left sided valves, resulting invariably in early neonatal death, unless *single ventricle* palliative procedure is undertaken to recruit the right ventricle to function as the systemic ventricle. Exceptionally the entire left heart may be hypoplastic without evidence of any structural obstruction. An obligatory atrial communication, or persistence of a decompressing vein that shunts pulmonary venous flow to the right side is mandatory for survival.

Hypoplastic left heart syndrome occurs in 0.16–0.36 per 1000 livebirths or 7–9% of all congenital heart defects. It is more common in boys.

ETIOPATHOGENESIS

Though its cause is multifactorial, familial cases with autosomal recessive, dominant and also X-linked modes of inheritance with variable penetrance and phenotypes have been reported. Increased occurrence has been noted in: Deletion of distal 11q (Jacobsen syndrome) and trisomies 13 and 18, besides Turner syndrome. Genetic mutations impairing prograde flow in developing left ventricle have been identified in 4 genes: *GJAI* (Connexin43, 6q22), cardiac transcription factor *NKX2-5* (5q35), *NOTCH1* (9q34) and *HAND1* (5q33). Moreover, definitive evidence has identified 8 genetic loci like 14q23 where a mutation results in HLHS and bicuspid aortic valve in the same family. The timing of the causative insult occurs during aortic and mitral valve development by limiting the blood flow through the left heart, which is vital for its development. Retrograde perfusion in the ascending aorta via patent ductus arteriosus (PDA) maintains the blood flow to the brain and coronary arteries (*duct dependent*).

Premature closure or absence of the patent foramen ovale (PFO) is a theoretical cause of HLHS as it prevents the inferior vena caval blood entering the left atrium; the fetal pulmonary blood flow alone is insufficient to promote development of the left heart structures.

Anatomic Considerations

Considerable variations in the size and nature of the aortic and mitral valves (atretic, hypoplastic or severely stenotic) are noted. It is important to exclude a supramitral membrane which when detected may change the management of the child. The mitral subchordal apparatus may be fused or have secondary chordae obstructing the outflow tract. In extreme cases, the whole left heart structures may be miniaturized with no functional components. The left ventricle is severely hypertrophied with a slit-like cavity, especially when the mitral valve is atretic. Endocardial fibroelastosis is often present depending on the degree of inflow and outflow tract obstruction. There is varying degree of subaortic or aortic valve obstruction with a narrow ascending aorta. Atrial or pulmonary venous anomalies including pulmonary vein obstruction or TAPVD may be associated.

PATHOPHYSIOLOGY

Fetal Circulation

In HLHS, the oxygenated placental blood from inferior vena cava (IVC) does not cross the fossa ovalis into the left atrium; instead, it mixes with the superior vena caval blood in the right atrium (RA). Obstruction in left heart, either at the mitral or aortic valve level, causes the pulmonary venous return to preferentially flow from the left atrium (LA) into the RA. The vena caval and pulmonary venous blood along with the coronary sinus flow enters the right ventricle and the pulmonary artery. A wide PDA and high pulmonary vascular resistance (PVR) drives most of the blood into the aortic arch. This flow is then distributed to the head and neck vessels, coronary arteries and the descending aorta. The distribution of blood into each vascular bed is determined by the relative resistance in each system. Thus the fetal circulation in HLHS differs from the normal fetus in the following manner:

- Larger PDA with higher PO₂
- Cerebral blood flow with relatively lower PO₂
- Higher PO₂ in the pulmonary arterial blood
- Retrograde coronary blood flow containing low PO₂ via a long curved channel from aortic arch supplying blood to the brain and upper body before supplying the coronaries.

Postnatal Circulation

The uniqueness of fetal circulation continues in the newborn with HLHS. The main changes at birth are the expansion of the lungs and increasing pulmonary blood flow delivered at systemic pressures. This leads to higher pulmonary venous return and increase in obligatory left to right shunt across the atrial septum. The right heart receives normal systemic venous return in addition to the increased pulmonary venous return. This causes the normally compliant right heart to dilate. Initially the RV systolic function is well maintained; but when stretched beyond the Starling curve, right heart dysfunction occurs with tricuspid valve regurgitation (TR).

Flow being inversely proportional to resistance (Ohm's law), the postnatal reduction in PVR occurring due to expansion of lung fields and regression of the pulmonary arterial wall thickness, leads to increased pulmonary blood flow. As the pulmonary blood flow increases, systemic blood flow, including coronary perfusion decreases, causing metabolic acidosis, decreased organ perfusion with oliguria and coronary ischemia. Unless the pulmonary blood flow is carefully controlled, the situation rapidly deteriorates, ending in cardiac arrest.

In HLHS, the sizes of the interatrial communication and ductus arteriosus determine the relative flow in systemic and pulmonary circulation, which in turn affects the systemic organ perfusion, coronary perfusion and pulmonary blood flow. The additional presence of varying degrees of arch hypoplasia and coarctation further compromises cerebral and retrograde coronary blood flow.

CLINICAL FEATURES

Neonatal Presentation

Most newborns with HLHS appear well at birth. The oxygen saturation is typically in the low 90s. As the PVR falls, tachypnea and tachycardia set in. Tachypnea with CO₂ washout further augments pulmonary blood flow and alveolar O₂ bringing the saturation to high 90s, a sign of impending cardiac decompensation. Vasoconstriction developing in neonates increases systemic vascular resistance (SVR) which in turn increases pulmonary blood flow. Feeble pulses and decreasing body perfusion with tachypnea, hypothermia, oliguria, or large liver are adequate reasons for Doppler ultrasound examination in neonates even before the development of lactic acidosis, pulmonary edema,

worsening saturation, ending in cardiac arrest. Murmur is rarely present due to TR. Very rarely a HLHS patient with restricted atrial communication and PDA may present at few weeks of age with severe pulmonary hypertension and desaturation.

Postnatal Diagnosis

Hypoplastic left heart syndrome must be suspected in any neonate, not diagnosed by fetal ultrasound presenting with tachypnea, tachycardia, feeble pulses and hypothermia. All such neonates should receive prostaglandin E1 infusion to maintain ductal patency while awaiting echocardiogram and parental decision for further referral and management. Other investigations may be supportive.

INVESTIGATIONS

Chest Radiograph

Cardiomegaly with increased pulmonary vascular markings; findings of pulmonary edema in the presence of restricted PFO or obstructed pulmonary veins. A large heart often suggests associated TR and right heart dilatation.

ECG

Sinus tachycardia with right-axis deviation, right atrial enlargement, and right ventricular hypertrophy with a qR configuration in the right precordial leads. Reduced LV forces, with ST-T wave changes suggestive of myocardial ischemia may be seen.

Echocardiography and Doppler Ultrasound

These reveal the following *diagnostic* information: Hypoplastic left ventricle and ascending aorta, the size of the mitral and aortic annulus; the length, morphology and function of LV, the mechanism of LVOT obstruction, the size of the ascending aorta, the morphology and mechanism of TR if present; the anatomy and direction of flow of the atrial communication, and direction of the ductal flow, and the presence and site of arch obstruction.

TREATMENT

The management of HLHS can be highly challenging as it involves continuous and compassionate care, staged palliation through multiple surgical interventions, frequent hospitalization, medications, and treatment of complications associated with significant mortality. Parents should be mentally prepared and encouraged to take treatment decisions by providing them with adequate details about each of these approaches and outcomes.

Initial Supportive Therapy in Neonatal Period

First Objective

Ductal patency is to be maintained to provide adequate blood flow to the systemic circulation and coronary perfusion by administering prostaglandin E1 infusion (5 ng/kg/min) with appropriate care and monitoring to avoid a significant dilatation of pulmonary circulation.

Second Objective

Pulmonary blood flow must be regulated so as to avoid an early onset of increased pulmonary vascular resistance (PVR). Factors affecting PVR include lung maturity, age, metabolic status, arterial PCO₂ and PO₂ levels, pH, cardiac functional status, the presence of TR, end diastolic pressure of the ventricles and restriction across the atrial septum. PVR is extremely sensitive to alveolar oxygen concentration. Hence, oxygen administration should not be based on hypoxia but the presence of parenchymal lung disease or pulmonary edema. Oxygen is best avoided if the lungs are normal and the neonate should be managed in room air.

Permissive hypercapnea with higher PaCO₂, an important aspect of managing PVR, often requires elective total ventilatory support by day 3 or 4 with hypoventilation, or the addition of nitrogen or carbon dioxide to the inspiratory circuit. Prior to intubation, the administration of nitrogen via hood may be practiced. Supportive measures are outlined in **Table 1**.

Surgery

Norwood (Stage I) Procedure (Palliative)

The main objectives are to control excess pulmonary blood flow and improve and maintain unobstructed systemic blood flow. Usually it is performed on day 5 of life with the falling of PVR in stabilized neonates on ventilator support. It consists of the following surgical maneuvers:

- Atrial septectomy to provide unrestricted atrial mixing
- PDA closure
- Creation of main pulmonary artery—aortic connection with a restrictive PA-aorta shunt placement to provide adequate pulmonary blood flow.

These stage I operated children with HLHS are managed in the same palliative manner as other congenital heart conditions with single ventricle with creation of bidirectional superior cavopulmonary artery anastomosis and subsequent completion of Fontan with a total cavopulmonary connection.

Sano modification of the Norwood procedure Increasingly adopted by many centers for better survival outcome between the first stage and cavopulmonary anastomosis, Sano procedure entails the insertion of a Gore-Tex graft between the RV and PA to provide restricted pulsatile pulmonary blood flow instead of a conventional modified aortopulmonary shunt. Major concerns include: single systemic RV scarring and branch pulmonary arterial distortions.

Hybrid and Other Approaches

Bilateral banding of the pulmonary arterial branches with stent placement in the ductus arteriosus is performed to reduce the high mortality associated with stage I Norwood reconstruction. In preterm babies with HLHS, long-term ductal patency with prostaglandin infusion instead of ductal stenting is rarely resorted to.

Transplantation

The alternative to staged Norwood procedure is neonatal heart transplantation with nearly similar survival outcomes and long-term complications. Fetal—prenatal interventions to prevent fetal hypoplasia of LH by relieving aortic valve stenosis or creating atrial septal defects are under investigation.

Table 1 Supportive measures in a newborn with hypoplastic left heart syndrome

Parameters	Medications	Monitoring
Metabolic acidosis	Sodium bicarbonate infusion	Serial arterial blood gas and acid-base, electrolytes
Oxygen saturations in the low 80s	Oxygen	
Systemic vasodilatation and regulation of PVR without compromising blood flow to other vital organs	Judicious use of inotropes, keeping in mind the potential benefits of vasodilatation in regulating PVR	Arterial pressures; ECHO Doppler studies
Diuretics	Renal perfusion	Adequate urine output

OUTCOME

Prenatal

The risk of intrauterine death is less than 5% and nearly half of pregnancies get terminated. Of the remaining 50–55%, the majority (80%) are born by normal vaginal delivery.

Postnatal

Without palliative surgery, all die within the first few weeks. In advanced countries, depending on the practice at a given cardiac center about 90% are palliated with Norwood or Sano procedure while others undergo hybrid procedure or heart transplantation; only a small proportion (10–15%) die preoperatively waiting for interventional treatment.

The 5-year survival of children born with HLHS after 3 major operations before school age and with the first 2 operations in their first year has significantly improved to around 60–70% with significant morbidity. Survivors exhibit reduction in exercise tolerance, delayed growth and motor development, low-normal intelligence, high-risk of sudden death, need for repeat hospitalizations, chronic medications and complications of single ventricle physiology.

IN A NUTSHELL

1. Hypoplastic left heart syndrome (HLHS) refers underdevelopment of the left heart structures, e.g., left atria, left ventricle, ascending aorta or the aortic arch.
2. Presence of an obligatory atrial communication or persistence of a decompressing vein that shunts pulmonary venous flow to the right side is mandatory for survival.
3. HLHS must be suspected in any neonate, presenting with tachypnea, tachycardia, feeble pulses and hypothermia.
4. All such neonates should receive prostaglandin E1 infusion to maintain ductal patency while awaiting echocardiogram and parental decision for further referral and management.
5. Early palliative surgery is recommended within first week of life.

Chapter 40.28

Pulmonary Arterial Hypertension

Nageswara Rao Koneti

Sir William Harvey was the first to describe importance of right ventricular (RV) function in 1616. However, for many years, the emphasis in the research was placed on the left ventricular (LV) physiology. The clinical importance of RV function in heart failure, congenital heart disease and pulmonary hypertension came into light only between 1950s and 1970s. The true incidence of idiopathic pulmonary arterial hypertension (IPAH) is unknown; however, 2.2 new cases per million per year are identified. Pulmonary arterial hypertension (PAH) may be idiopathic or secondary. PAH secondary to congenital and other structural or systemic disease is still the leading causes globally. The etiology of IPAH is unknown and poorly understood. The diagnosis is by exclusion after complete evaluation to rule out secondary causes. The natural history of IPAH appears to be still guarded even in this era. The National Institutes of Health Registry showed over all median survival of 2.8 years after the diagnosis, whereas in children median survival after diagnosis is reported to be only 10 months. However, the prognosis appears to be slightly better with the current understanding and available medications.

DEFINITION

Pulmonary hypertension (PAH) is defined as mean pulmonary arterial pressures more than 25 mm Hg at rest or more than 30 mm Hg during exercise. Neonates and infants below 3 months of age are excluded in the definition due to physiological interference of neonatal pulmonary vascular resistance.

Persistent pulmonary hypertension of newborn is a pulmonary parenchymal disease due to various mechanisms leading to maladaptation in the postnatal period or in utero due to unknown mechanism. This condition is characterized by increased pulmonary vascular resistance, severe hypoxemia and right to left shunt across foramen ovale and arterial ductus.

Hyperkinetic pulmonary hypertension is due to increased pulmonary blood flow, congenital heart disease, e.g., ventricular septal defect. Pulmonary venous hypertension is caused by either obstruction or dysfunction in the left side of the heart leading to increased pulmonary capillary wedge pressures (postcapillary pulmonary hypertension), e.g., mitral stenosis, LV dysfunction, etc. Pulmonary vascular disease due to congenital heart disease will be developed over the period of time due to left to right shunt referred as Eisenmenger syndrome.

Clinical classification of pulmonary hypertension is shown in **Box 1**. The clinical conditions with PAH are classified according to pathological, pathophysiological and therapeutic characteristics into five groups (4th World Symposium on PAH, 2008).

PATHOPHYSIOLOGY

Pulmonary arterial hypertension is a disease of pulmonary vascular tone. The important features are abnormal muscularization of distal pulmonary arteries at the alveolar duct and wall levels and reduction in their number. Progressive intimal hyperplasia is commonly seen in older children and adults leading to plexiform lesions and occlusive changes (**Figs 1A to C**). PAH is a vasculopathy involving small arteries and arterioles. The changes include

BOX 1 Causes and nice clinical classification of pulmonary hypertension (modified from past Dana Point classification)

- Pulmonary arterial hypertension
 - Idiopathic PAH
 - Heritable PAH
 - BMPR2
 - ALK-1, ENG, SMAD9, CAV1, KCNK3
 - Unknown
 - Drug and toxin induced
 - Associated with:
 - Connective tissue disease
 - HIV infection
 - Portal hypertension
 - Congenital heart diseases
 - Schistosomiasis
 - Pulmonary veno-occlusive disease and/or pulmonary capillary hemangiomatosis
 - Persistent pulmonary hypertension of the newborn (PPHN)
- Pulmonary hypertension due to left heart disease
 - Left ventricular systolic dysfunction
 - Left ventricular diastolic dysfunction
 - Valvular disease
 - Congenital/acquired left heart inflow/outflow tract obstruction and congenital cardiomyopathies
- Pulmonary hypertension due to lung diseases and/or hypoxia
 - Chronic obstructive pulmonary disease
 - Interstitial lung disease
 - Other pulmonary diseases with mixed restrictive and obstructive pattern
 - Sleep-disordered breathing
 - Alveolar hypoventilation disorders
 - Chronic exposure to high altitude
 - Developmental lung diseases
- Chronic thromboembolic pulmonary hypertension (CTEPH)
- Pulmonary hypertension with unclear multifactorial mechanisms
 - *Hematologic disorders*: Chronic hemolytic anemia, myeloproliferative disorders, splenectomy
 - *Systemic disorders*: Sarcoidosis, pulmonary histiocytosis, lymphangioma, leiomyomatosis
 - *Metabolic disorders*: Glycogen storage disease, Gaucher disease, thyroid disorders
 - *Others*: Tumoral obstruction

Abbreviation: PAH, pulmonary arterial hypertension.

intimal hyperplasia, medial hypertrophy, adventitial proliferation, thrombus formation in the distal arterioles, inflammation and finally leading to plexiform arteriopathy.

There will be progressive increase of RV pressure overload leading to RV hypertrophy and dilatation. This afterload mismatch (maladaptation) in the right heart will eventually cause decompensated heart failure. The natural history of PAH with this presentation will have poor prognosis. The progressive increase in pulmonary vascular resistance (PVR) will have impact on the right atrial pressures, cardiac index. These three parameters are determinants of RV function. The RV is thinner than LV and the length of the LV is more than RV. The difference between both RV and LV is 3:1. The shape of the RV is complex in contrast to ellipsoidal shape of LV. The septum is concave toward LV in both systole and diastole. The volume of RV is larger than LV and RV mass is approximately one-sixth that of LV. The RV is mainly composed of superficial and deep muscle layers with different orientation. The arrangement of myofibers is different in RV. Heavily trabeculated RV wall is due to incompletely compacted endocardium. There will be changes in the adrenergic pathway of RV myocytes leading to reduced contractility. Hence, RV is more vulnerable for the stress and early failure is seen due to maladaptation.

Figures 1A to C (A) Normal distal pulmonary arteriole cross section; (B) Proliferation of smooth muscle cells and endothelial cells; (C) Complex vascular lesion: (a) normal distal pulmonary arteriole; (b) stage of vasoconstriction leading to smooth muscle hypertrophy and early intimal proliferation; (c) advanced vascular lesions producing adventitial and intimal proliferation and plexiform lesions

CLINICAL PRESENTATION

There should be high degree of clinical suspicion to diagnose PAH. This condition may mimic other pulmonary disorders. The diagnostic work-up should include a thorough clinical evaluation, laboratory evaluation including both noninvasive and invasive evaluation since IPAH is a diagnosis of exclusion (**Flow chart 1**).

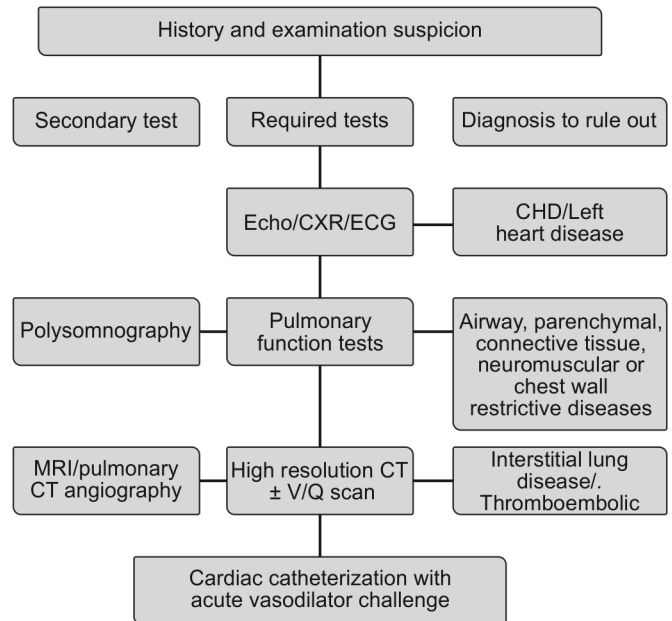

Most of the children present with nonspecific and atypical symptoms. Symptoms during exercise are common related to fixed cardiac output due to distal pulmonary vascular resistance. Breathlessness, easily fatigability and syncope are commonly noticed. Angina may be a rare symptom due to RV hypertrophy probably due to more myocardial demand. RV failure may produce symptoms like abdominal pain and distension due to hepatic congestion and stretching of the liver capsule. Physical signs include distended jugular veins with prominent *a* wave and subsequently *v* becomes taller due to development of RV dysfunction and tricuspid regurgitation. Cardiovascular examination generally shows parasternal heave, epigastric lift and cardiomegaly. The pulmonary component of second heart sound is loud and constant ejection click due to dilated pulmonary artery is usually appreciable. RV third heart sound generally suggests development of RV dysfunction. A pansystolic murmur of tricuspid regurgitation may be heard at the lower left sternal border and a diastolic murmur of pulmonary insufficiency is better appreciated during inspiration. Jaundice, edema and ascites are present in advanced stage of decompensated heart failure.

INVESTIGATIONS

Chest X-ray

The increase in cardiothoracic ratio is seen in latter part of the PAH. The RA and RV may be enlarged. The central pulmonary dilation with peripheral pruning is commonly noted (**Fig. 2**). Pulmonary arterial calcification is extremely rare and seen in secondary causes. Associated parenchymal changes are seen in lung disorders. Telltale evidence of past increased pulmonary blood flow may be seen in cases with congenital heart disease producing

Flow chart 1 Screening/diagnostic algorithm for pediatric PAH

Figure 2 Chest X-ray of a child with pulmonary hypertension showing dilated central pulmonary arteries

PAH. Evidence of pulmonary venous hypertension gives clue to the diagnosis of left heart disease.

Electrocardiogram

Electrocardiogram (ECG) may provide clues to support the diagnosis of PAH. Right atrial enlargement, RV hypertrophy and right axis deviation are commonly seen (**Fig. 3**). Monophasic R in V1 and qR in V1 are generally suggestive of systemic or suprasystemic pulmonary artery pressures (PAPs). Arrhythmias are rare however, atrial arrhythmias include ectopic atrial rhythm, and flutter or fibrillation is common than ventricular arrhythmias.

Echocardiography (Figs 4A to D)

The assessment includes: (a) estimation of PAP, (b) assessment of RV function, and (c) assessment of severity of valvar regurgitations.

Figure 3 Electrocardiogram of a child with severe pulmonary hypertension showing right axis deviation and right ventricular hypertrophy as evidenced by tall R waves in V1

Estimation of Pulmonary Artery Pressure (PAP)

- This is based on the peak velocity of the jet of tricuspid regurgitation. The modified Bernoulli equation: $4v^2$ ($4 \times \text{TR velocity}$) + RA mean pressure. The PAP may be underestimated in case with RV dysfunction; hence, assessments of other parameters are helpful in diagnosis and estimation of severity of PAH.
 - Calculation of mean PAP from pulmonary regurgitation: mean PAP = $0.61 \times \text{PA systolic pressure} + 2 \text{ mm Hg}$.
- The right atrium, RV and pulmonary artery are dilated. Straightening of interventricular septum or D-shaped septum is seen in severe PAH. The LV function is usually preserved; however, size of the LV may be smaller in cases with suprasystemic PAH due to bowing of interventricular septum to LV.

Assessment of Right Ventricular Function

Quantitative assessment of RV function is quite challenging due to geometry of the RV. Several parameters are available for the assessment of RV function but none is accurate.

- Tei index (myocardial performance index)** The myocardial performance index is the ratio of isovolumic time intervals to ventricular ejection time. This index is independent of preload, afterload and heart rate. The normal value is 0.28 ± 0.04 and increases in the presence of RV dysfunction.
- Tricuspid annular plane systolic excursion (TAPSE)** This is a measure of longitudinal function of RV and measured from the tricuspid lateral annulus. TAPSE less than 16 mm indicates RV systolic dysfunction.
- RV ejection fraction (RVEF)** RVEF is highly dependent on loading conditions and may not reflect actual contractility. The normal range varies between 40% and 76%. Magnetic resonance imaging is the most accurate method to assess RVEF.

- RV fractional area** Two-dimensional area less than 35% indicates RV systolic dysfunction.

MRI and High Resolution CT Scans

High-resolution computed tomography (HRCT) is useful in diagnosing parenchymal lung disease and pulmonary veno-occlusive disease or isolated pulmonary vein obstruction (**Fig. 5**).

Pulmonary Function Tests

Airway diseases and other lung parenchymal diseases can be assessed by pulmonary function tests (PFT).

Six-minute Walk Test

Six-minute walk test is a useful in assessing functional capacity of the patient. It is a good clinical test to see the treatment response during follow-up assessment. A walking distance of greater than 380 m during treatment suggests good response whereas less than 330 m suggests impaired prognosis.

Ventilation-perfusion Scintigraphy

This is a good screening test to rule out pulmonary thromboembolism. Coagulation disorders, elderly, patients with deep vein thrombosis and on oral contraceptive people are at high risk for pulmonary thromboembolism. VQ mismatch and multiple perfusion defects are generally seen in chronic pulmonary thromboembolism.

Laboratory Investigations

Routine complete blood picture, liver function test as a baseline in case of right heart failure or prior to the starting of endothelin receptor antagonists or phosphodiesterase-5 inhibitors is mandatory. Other necessary laboratory tests are indicated based on the clinical suspicion of other diseases.

Figures 4A to D Transthoracic echocardiogram showing: (A) Dilated right heart in apical four-chambered view; (B) D-shaped left ventricle (LV) and dilated right ventricle (RV); (C) RV systolic pressure by tricuspid velocity jet showing severe pulmonary hypertension; (D) Tricuspid annular plane systolic excursion (TAPSE) by M-mode showing significantly reduced suggestive of RV dysfunction

Figure 5 Computerized tomography angiogram showing left pulmonary venous (LPV) obstruction in a child with pulmonary hypertension

Cardiac Catheterization

A routine diagnostic cardiac catheterization is not indicated since the subset of population is sick and high-risk for sudden cardiac death during cardiac catheterization. Good patient preparation and control of heart failure prior to the vasodilator response test in the catheterization laboratory reduce the risk of complications.

The right heart study includes assessment of cardiac output and estimation of pulmonary vascular resistance.

MANAGEMENT

The use of newer medications modified the prognosis in recent times. Aggressive use of PAH targeted therapy has significantly changed the outcome and symptomatic status (**Flow chart 2**).

General Measures

Physical exercise should be avoided even in asymptomatic patients since exercise cardiac output can not be maintained. High altitudes should be avoided above 1,500 m of sea level and necessarily should be supplemented with oxygen. All respiratory infections should be treated promptly since significant mortality is associated with pneumonia. Vaccination against influenza and pneumococcal should be considered.

Supportive Treatment

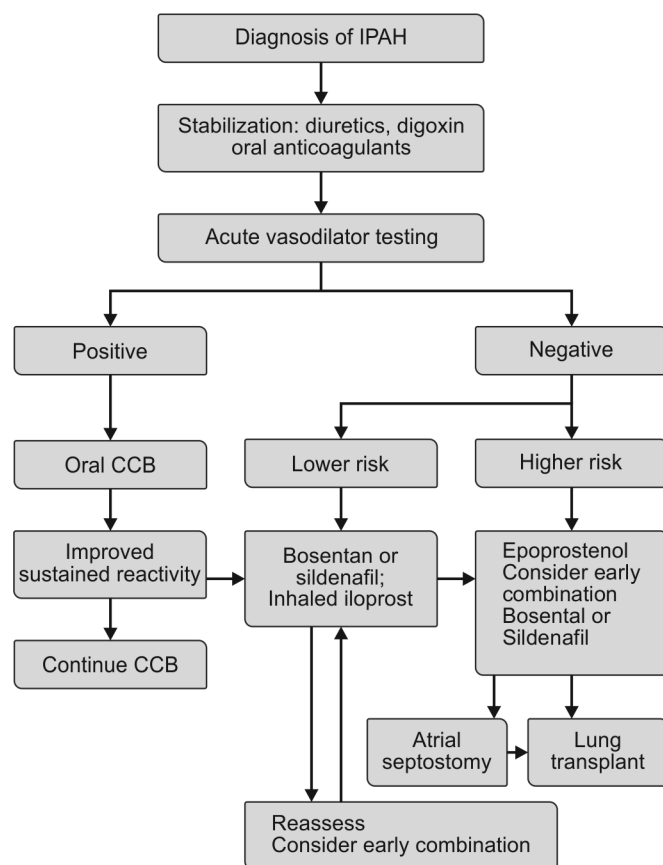

Diuretics

Diuretics should be considered in cases with decompensated heart failure and RV dysfunction. Care should be taken not to deplete the intravascular volume since cardiac output is predominantly preload dependent in the right side. Combination of furosemide and spironolactone are usually recommended.

Digoxin

Impaired RV function is generally seen in the later part of the PAH. Inotropic support may be helpful to some extent in the advanced

Flow chart 2 Treatment algorithm for the management of pediatric idiopathic pulmonary arterial hypertension (IPAH)

Abbreviations: CCB, calcium channel blockers; IPAH, idiopathic pulmonary arterial hypertension.

cases. Digoxin may also be indicated in case of supraventricular tachyarrhythmia to slow the ventricular rate.

Oral Anticoagulants

Although there is no definitive data to suggest the beneficial effects, Warfarin has been shown to be associated with improved survival. Oral anticoagulant (OAC) may prevent secondary thrombosis in the pulmonary arteries with low pulmonary blood flow due to high pulmonary vascular disease. The international normalization ratio (INR) may be adjusted to minimal range between 1.3 and 1.5.

Targeted Specific Treatment

Calcium Channel Blockers

Nearly 10% of the patients with PAH show response to acute vasodilator testing in the catheterization. The vasodilator testing can be performed using intravenous epoprostenol, adenosine or inhaled nitric oxide (NO). A decrease in pulmonary artery pressure of greater than 20% or pulmonary vascular resistance greater than 30% is usually considered as positive response and beneficial from long-term calcium channel blocker treatment. Either amlodipine or nifedipine or diltiazem has been used. These medications should be avoided in children less than 1 year of age due to negative inotropic effect.

Prostanoids

Intravenous epoprostenol It has been shown improved survival in patients with PAH. The medication is expensive and hence limits its usage in India. The medication is delivered by infusion pumps through long peripherally inserted central catheters. The starting dose is 2–4 ng/kg/min and increased to target dose of 10–15 ng/kg/min for 2–4 weeks. The side effects include headache, flushing, diarrhea, nausea and vomiting.

Iloprost An inhaled prostacyclin analog with half-life of 20–25 min has shown beneficial effects on symptomatology and quality of life. The major advantage is its selective nature on pulmonary vasodilatation and less effect on the systemic blood pressure.

Beraprost This is an orally available prostacyclin analog. The medication is not available in USA and India due to its inconsistent results in two different clinical trials.

Endothelin Receptor Antagonists

Endothelin receptors exist in two isoforms, ET_A and ET_B. Smooth muscle cells are responsible for vasoconstriction due to ET_A receptors. The ET_B receptors mediate endothelium-dependent vascular relaxation by inducing NO and prostacyclin release. This induces vasodilatation. Bosentan is a dual endothelial receptor antagonist and has been studied in patients with PAH. Two randomized double-blind, placebo-controlled studies showed improvement of six-minute walk test, symptomatic status and reduction in mortality. The suggested dosage was 31.25 mg between 10 kg and 20 kg, 62.5 mg between 20 kg and 40 kg and 125 mg for more than 40 kg. In FUTURE-1 study, bosentan dose was 2 mg/kg twice daily in the first 4 weeks and the 4 mg/kg twice daily for 8 weeks. Bosentan is metabolized in the liver and hence assessment of liver functions baseline and periodically every 4–6 weeks is mandatory.

Phosphodiesterase-5 Inhibitors

Increase concentration of cGMP in the smooth muscles of the pulmonary vessels produces smooth muscle relaxation and subsequently pulmonary vasodilatation. Sildenafil is a selective inhibitor of cGMP phosphodiesterase type 5, leading to increase cGMP in the pulmonary vasculature. Sildenafil can be used in children with PAH in the dose of 0.5–1 mg/kg/dose for three to four times a day. The main side effects are erections and systemic hypotension when high doses are used. Tadalafil is another phosphodiesterase-5 inhibitor and can be used once in a day; however, its usage in pediatric population has not been established.

Combination Therapy

A combination of two or more drugs appears to be reasonable since there are three different intracellular pathways that include: (i) NO, (ii) prostacyclin and (iii) endothelin. It is probably safer to start with one medication and second drug may be started based on the response. The combination of sildenafil and inhaled iloprost appears more potent.

Other Procedures

Balloon atrial septostomy The natural history of Eisenmenger syndrome appears to be better than IPAH. Blade balloon atrial septostomy allows right to left shunt at atrial level and decompresses right atrium and RV with improvement of clinical signs and symptoms of right heart failure.

Lung transplantation Lung transplantation is indicated in selected cases of advanced heart failure. The availability of donor, technical difficulties and allograft rejection limit the therapy even in western countries.

PROGNOSIS AND SURVIVAL

Netherlands Registry

The yearly incidence of PAH was 63.7 cases per million children. The annual incidence of IPAH and PAH due to congenital heart disease was 0.7 and 2.2 cases per million respectively. The estimated median survival of children was 4.12 years prior to the availability of targeted treatment. With the available pulmonary vasodilators, the survival rate has been shown somewhat improvement. The REVEAL registry showed 1-, 3- and 5-year estimated survival rates of $94 \pm 4\%$, $84 \pm 5\%$ and $74 \pm 6\%$, respectively. Poor prognostic factors include: history of syncope, clinical heart failure, failure to thrive, > Class III, pericardial effusion, right heart dysfunction, elevated brain natriuretic peptide (BNP), right atrial mean pressure greater than 10 mm Hg and pulmonary vascular resistance index (PVRI) greater than 20.

IN A NUTSHELL

1. Pulmonary hypertension (PAH) is defined as mean pulmonary arterial pressures more than 25 mm Hg at rest or more than 30 mm Hg during exercise. Neonates and infants below 3 months of age are excluded in the definition.
2. PAH may be idiopathic or secondary.
3. PAH secondary to congenital and other structural or systemic disease is still one of the leading causes globally.
4. The etiology of IPAH is unknown and poorly understood.
5. The diagnosis is by exclusion after complete evaluation to rule out secondary causes.
6. The natural history of IPAH appears to be still guarded with overall median survival of only 10 months.

Chapter 40.29

Acute Rheumatic Fever

B Anjaiah

Acute rheumatic fever is an inflammatory autoimmune disorder that affects several organs of the body characterized by arthritis, carditis, chorea, rheumatic nodules, erythema marginatum and fever caused by group A β -hemolytic *Streptococcus* (GABHS).

ETIOLOGY

Acute rheumatic fever is exclusively caused by GABHS, a gram-positive organism. Lancefield classified group A β -hemolytic streptococci into serologic types on the basis of the M protein. The M protein is the most important because it determines the virulence of the organism, stimulates the formation of opsonizing and precipitating antibodies. Serotypes such as M types 1, 3, 5, 6, 14, 18 and 24 have been associated with rheumatic fever. Group C and G streptococci may also contribute to acute rheumatic fever.

EPIDEMIOLOGY

Geographical Distribution

The incidence of acute rheumatic fever is more common in countries with tropical climate, particularly in developing countries. There is a decline in the incidence of acute rheumatic fever in industrialized countries, but its prevalence in developing countries of the world was very high. More than 80% of the world's cases of acute rheumatic fever and rheumatic heart disease (RHD) occur in people living in developing countries. The reasons are poverty, unhygienic environments, lack of accessibility to medical care and household overcrowding. Recently, the prevalence of rheumatic fever has shown a steep decline in Indian settings.

Incidence

The incidence of acute rheumatic fever varies with geographic location and the population ranges from 3 to 61 per 100,000 school children. The incidence of rheumatic fever in Indian children by echo studies is 0.5–11 per 1,000.

Sociodemographic Characteristics

The vulnerable age group for development of acute rheumatic fever is 5–15 years, but it is rare below 4 years of age. There is no difference in the incidence of acute rheumatic fever between males and females, but the incidence of chorea and RHD are more in females. Acute rheumatic fever is most common during winter and spring, a seasonal variation similar to that of streptococcal pharyngitis. The incidence of initial attacks of acute rheumatic fever is more in disadvantaged population, presumably because crowded living conditions that facilitate the spread of streptococcal infection.

Genetics

Genetic predisposition of individual plays an important role in pathogenesis of the disease. DR4 allele is found in Indian, American Caucasian and Saudi-Arabian patients. DR7 is found in Brazil and Turkey.

PATHOGENESIS

Pathogenesis of relationship between acute rheumatic fever and group A β -hemolytic streptococcal infection is not clear. Acute rheumatic fever is supposed to be an autoimmune disease in which invasive streptococcal infection evokes an antibody response from

the host and this antibody attacks antigenically similar host tissues (**Flow chart 1**). Four streptococcal host cross-reactive antigen-antibody systems have been identified.

1. Cardiac myofibrillar smooth muscle antigen cross-reacting with streptococcal cell wall and cell membrane antigen.
2. Heart valve fibroblast antigen cross-reacting with streptococcal cell membrane antigen.
3. Subthalamic and caudate nuclei antigen cross-reacting with streptococcal cell membrane antigen.
4. Heart valve and connective tissue antigen cross-reacting with streptococcal group A carbohydrate antigen.

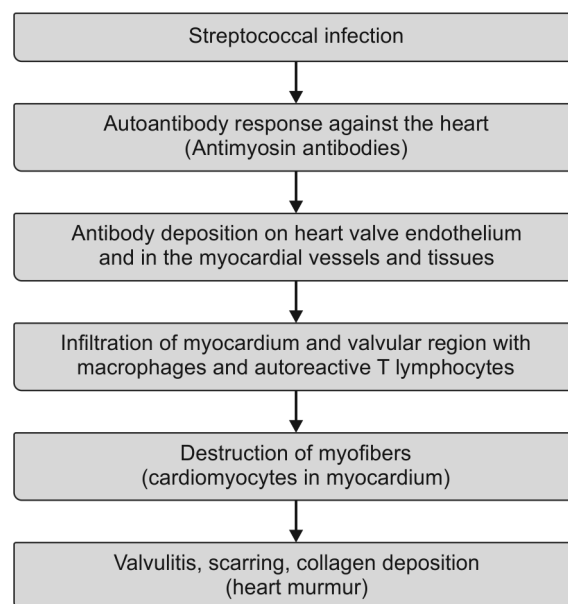

It is also possible that streptococcal extracellular products play a role in the pathogenesis of acute rheumatic fever.

PATHOLOGY

In acute rheumatic fever, immunological events cause proliferative and exudative inflammatory reactions in the connective tissues of the affected organs. These lesions are more distinctive within the heart but also involve joints, subcutaneous tissues, brain and vessels of the lung. The pathological hallmark of rheumatic carditis is pancarditis involving pericardium, myocardium and endocardium. The histopathological hallmark of carditis is the presence of Aschoff body in the interstitium. Pericarditis is characterized by the deposition of a serofibrinous exudate, giving the so-called bread-and-butter appearance. It heals with no significant adhesions and constriction. The ventricles and atria are often enlarged. Myocardium is edematous and shows nonspecific inflammation. There is no evidence of cell damage. Myocardium is infiltrated with lymphocytes, macrophages and other inflammatory cells. Endocardial inflammatory changes are responsible for the valvulitis. Small, 1–2 mm, friable, fibrinous, verrucous vegetations may occur on the atrial surface of the mitral valves or on the ventricle side of the aortic valves or at sites of valve closure. It is infiltrated with histiocytes and lymphocytes. It may result in mitral stenosis (MS), mitral regurgitation (MR) or aortic regurgitation (AR). There is a fibrotic thickening of the posterior left atrial wall called *McCallum's Patch*.

Generalized vasculitis involving coronary arteries and the aorta can be seen. Histology of subcutaneous nodules reveals

Flow chart 1 Hypothesis of the immunopathogenesis of acute rheumatic fever

central fibrinoid necrosis surrounded by histiocytes, fibroblasts, occasionally lymphocytes and rarely polymorphs.

CLINICAL FEATURES

Arthritis, carditis, chorea, subcutaneous nodules and erythema marginatum constitute the major manifestations of acute rheumatic fever. Arthritis, carditis and erythema marginatum are the acute major manifestations whereas subcutaneous nodules and chorea are the late manifestations. A patient may present with one, two or more of these manifestations with varying severity. The minor manifestations are fever, arthralgia, abdominal pain, abnormal acute phase reactants and prolonged PR interval.

Polyarthritis

Arthritis occurs in 40–70% of patients of acute rheumatic fever. It is one of the major manifestations of acute rheumatic fever. Major joints like knees, ankles, wrists and elbows are commonly involved. Rarely, small joints like metacarpophalangeal, spine and temporomandibular may be involved. The arthritis of acute rheumatic fever is characteristically migratory and fleeting. The joints are swollen, hot, red and tender. The pain moves from one joint to the other over a period of hours. The duration of arthritis is 2–4 weeks and spontaneous resolution occurs without residual defects exception being Jaccoud's arthritis in which there is an erosion of the metacarpal heads resulting in hook-like deformities which is extremely rare. Arthralgia without joint involvement usually affects large joints in the same migratory pattern.

Carditis

Cardiac inflammation develops in 50% of the patients. High frequency of this manifestation develops in developing countries. Pancarditis is the hallmark of rheumatic carditis (**Table 1**). Carditis is the most common cause of morbidity and mortality with varied manifestations. It may be associated with other manifestations like arthritis, subcutaneous nodules, etc., in some patients it may be subtle. RHD occurs at a much younger age in India as compared to Western countries and structural stenosis or incompetence of the mitral valve occurs very frequently in young children. Juvenile MS has been reported from all developing countries and its mechanism is not known.

Mitral valve involvement presenting as MR occurs in 92–95% of patients with carditis. Mitral valve involvement is observed in 70–75% of patients with endocarditis. Aortic valve involvement in rheumatic carditis presents as AR occurs in 20–25% of patients and it is an isolated finding in 5–8%. Tricuspid valve involvement is seen in 30–50% of patients. Involvement of pulmonary valve is rare. Pericarditis occurs in approximately 4–11% of patients with acute rheumatic carditis.

Table 1 Clinical features of acute pancarditis in acute rheumatic fever

Involvement	Clinical features
Pericarditis	<ul style="list-style-type: none"> • Precordial chest pain • Friction rub • Effusion
Myocarditis	<ul style="list-style-type: none"> • Cardiomegaly • Tachycardia • Congestive heart failure • Soft first heart sound • S₃ gallop
Endocarditis	<ul style="list-style-type: none"> • Apical pansystolic murmur • Apical mid-diastolic murmur (Carey Coombs murmur) • Basal early diastolic murmur

Subclinical (Silent) Carditis

There is an entity called subclinical carditis in which silent carditis is found in patients with isolated arthritis and/or pure chorea, without auscultatory findings of valvar dysfunction. There is a pathological pattern of valvar regurgitation and thickening of the valvar leaflets revealed by Doppler echocardiography. Mild degrees of MR and/or AR are most commonly described in rheumatic subclinical carditis. These patients require secondary prophylaxis treatment to prevent progression of the valvar lesion.

Chronic Rheumatic Fever

In most attacks of acute rheumatic fever, clinical and laboratory evidence of inflammatory activity usually subside within 6 months. In some patients, evidence of rheumatic activity persists for a much longer time without recurrent streptococcal infection. A long duration was defined as an inflammation lasting for more than 223 days termed as *chronic RF*. There is a clinical activity of arthritis or arthralgia and tachycardia.

Subcutaneous Nodules

Subcutaneous nodules occur as painless, small (0.5–2 cm), mobile lumps beneath the skin overlying bony prominences such as ulnar borders of forearms, knuckles, shin of tibia, occipital region (**Fig. 1**) and spinal process of vertebrae. They are a delayed manifestation of rheumatic fever and appear around 6 weeks after the onset of rheumatic fever. They are associated with severe carditis. These occur in 0–10% of the patients of acute rheumatic fever and sometimes it may be an isolated major manifestation. Spontaneous resolution occurs in 2–3 weeks without residual lesions.

Erythema Marginatum

These occur in 5% of patients. It is uncommon in Indian reports of children with acute rheumatic fever probably because the evanescent lesion might not be recognized because of the brown or dark skin color of our population or might not be appreciated as important to seek medical attention by their parents. It is associated with carditis and subcutaneous nodules. It appears only in patients with carditis. If present, it is virtually a sign of rheumatic fever.

Sydenham Chorea (St. Vitus Dance)

The incidence of Sydenham chorea in children with acute rheumatic fever is less than 15%. There is an inflammatory involvement of subthalamic and caudate nuclei of central nervous system. It is a delayed manifestation (1–7 months) of rheumatic fever which has a female predilection and increases after puberty. The important features are involuntary movements which are abrupt, sudden,

Figure 1 A boy with occipital subcutaneous nodules

quasi-purposive, nonrepetitive and jerky movements, hypotonia and muscle weakness mainly involving the distal parts of the body and emotional instability. The important signs are darting tongue or jack-in-the box tongue or snake tongue flicks, hyperpronation of the raised hands, choreic hand in the extended hands, milkmaid grip and dancing gait (**Figs 2A and B**). It can be associated with carditis but not with arthritis. Hemichorea and chorea gravidarum are known variants.

Other Manifestations

Fever is seen in early stages of acute rheumatic fever and lasts usually for less than 2 weeks and rarely exceeds beyond 39°C. Anemia, epistaxis, weight loss and pallor are the other manifestations. Abdominal pain can be due to nonspecific mesenteric adenitis or due to congestive hepatomegaly. Only arthralgia can be there; joint pain involves large joints, asymmetrical, migratory, rarely incapacitates and lasts less than 2 weeks. There is a high correlation with severe carditis.

Table 2 lists the diseases to be considered in the differential diagnosis of acute rheumatic fever.

DIAGNOSIS

The diagnosis of acute rheumatic fever is considered on the basis of WHO adoption of (2004) revised Jones criteria, 1992 (**Tables 3 and 4**) and ancillary studies.

Ancillary Studies

Studies to Support Recent Group A β -Streptococcal Infection

- Increasing antistreptolysin O (ASO) titer from the end of 1 week and reaching the peak level by 3–6 weeks following infection. In children, 1:333 and in adults 1:250 are often considered as significant titer indicative of recent group A β -streptococcal (GABS) infection.
- Anti-DNase B titers rise 1–2 weeks of infection and reach the peak levels 6–8 weeks after infection.
- Culture of the organisms from throat is also important.

Tests to Support Inflammatory Process

- Erythrocyte sedimentation rate (ESR):** There is an increase in plasma fibrinogen secondary to inflammation causing an elevated ESR.
- C-reactive protein (CRP):** It is elevated promptly in inflammatory process and is not affected by congestive heart failure (CHF).

Table 2 Differential diagnosis of acute rheumatic fever

Arthritis	Carditis	Chorea
Rheumatoid arthritis	Kawasaki disease	Huntington chorea
Systemic lupus erythematosus	Viral myocarditis	Wilson disease
Serum sickness	Viral pericarditis	Systemic lupus erythematosus (SLE)
Sickle cell disease	Congenital heart disease	Tics
Postinfective reactive arthritis	Innocent murmur	Hyperactivity
(<i>Shigella</i> , <i>Salmonella</i> , <i>Yersinia</i>)		
Leukemia		

Table 3 WHO adoption of (2004) revised Jones criteria of 1992

Clinical and laboratory criteria	Supportive evidence of preceding streptococcal infection
Major criteria (more specific) <ul style="list-style-type: none"> • Polyarthritis • Carditis • Chorea • Subcutaneous nodules • Erythema marginatum Minor criteria (less specific) <ul style="list-style-type: none"> • Fever • Polyarthralgia • ESR, CRP, leukocytosis • ECG: prolonged PR interval 	<ul style="list-style-type: none"> • ASO • Antideoxyribonuclease • History of (within previous 45 days) streptococcal sore throat • Scarlet fever • Positive throat culture • Positive rapid streptococcal antigen detection test

Abbreviations: ASO, antistreptolysin O; ESR, erythrocyte sedimentation rate; CRP, C-reactive protein; ECG, electrocardiogram.

Table 4 WHO criteria for diagnosis of acute rheumatic fever and rheumatic heart disease

S. No.	Diagnostic categories	Criteria
1.	Primary episode of rheumatic fever	Two major or one major and two minor manifestations plus evidence of a preceding GABS infection, streptococcal infection
2.	Recurrent attacks of rheumatic fever in a patient without established rheumatic heart disease	As for a primary episode of rheumatic fever
3.	Recurrent attack of rheumatic fever in a patient with established rheumatic heart disease	Two minor manifestations plus evidence of a preceding group A streptococcal infection
4.	Rheumatic chorea	Other major manifestations or evidence of group A streptococcal infections are not required because these are delayed manifestations of streptococcal infection
5.	Insidious onset of rheumatic carditis. Chronic valve lesions of rheumatic heart disease, i.e., patients presenting for the first time with pure MS or mixed mitral valve disease with or without aortic valve disease	Do not require any other criteria to be diagnosed as having rheumatic heart disease

Abbreviations: GABS, group A β -streptococcal; MS, mitral stenosis.

Tests Suggestive of Pancarditis

- X-ray chest to identify the cardiac enlargement and congestion of the lungs in carditis.
- *Electrocardiography for presence of any of the following findings:* (a) sinus tachycardia, (b) prolonged PR interval and (c) ST segment and T-wave changes of acute pericarditis.
- *Echocardiography:* Two dimensional echocardiography is central to the diagnosis and should be performed in all patients of acute or chronic RHD. It can identify pericarditis with pericardial effusion, myocarditis, enlargement of cardiac chambers and involvement of mitral valves, aortic valves, and right sided valves which may manifest as regurgitation.
- *Cardiac catheterization:* Cardiac catheterization and angiography are rarely necessary for the management of patients with acute rheumatic valvar disease.

MANAGEMENT

All children with suspected carditis in acute rheumatic fever need to be admitted, investigated, monitored and treated appropriately as the carditis is getting confirmed.

Antibiotic Therapy

Once the diagnosis of acute rheumatic fever has been established, the affected children must be given 10 days of orally administered penicillin or erythromycin or a single intramuscular injection of benzathine penicillin regardless of the throat culture results to eradicate GABS from the upper respiratory tract. After this initial course of antibiotic therapy, they will be started on long-term antibiotic prophylaxis.

Anti-inflammatory treatment is summarized in **Table 5**.

Rest and Ambulation

Rest and graded ambulation is suggested as per the severity of the lesion. They are allowed to ambulate as soon as the signs of acute inflammation have subsided. Patients with carditis require longer periods of bed rest.

COURSE AND PROGNOSIS

In 1884, Lasague noted that *rheumatic fever* is a disease that *licks the joints and bites the heart*. The sequelae depend upon the severity of involvement of the heart. Arthritis and chorea have good prognosis. If carditis is limited to systolic murmur, only 25% of patients are left with residual heart disease. The patient with congestive cardiac failure develops chronic valvar heart disease over a period of 5–10 years. Death during acute attack is rare in the past 30 years due to availability of better awareness and seeking early treatment facilities

Table 5 Treatment of acute rheumatic fever

Clinical condition	Anti-inflammatory drug
Arthralgia	Any analgesic can be used
Arthritis	Aspirin 100 mg/kg/day in divided doses for 2 weeks followed by 75 mg/kg/day in divided doses for 4–6 weeks
Carditis with cardiomegaly or CHF	Prednisolone 2 mg/kg/day in divided doses for 2 weeks and taper to stop it in another 2 weeks. At the time of tapering of corticosteroids introduce aspirin 75 mg/kg/day in divided doses for 4–6 weeks to prevent rebound phenomena
CHF	<i>Antifailure measures:</i> Bed rest, diuretics, digoxin, salt-restricted diet
Chorea	Sodium valproate, haloperidol can be given

Abbreviation: CHF, congestive heart failure.

in a hospital. Average attack of acute rheumatic fever lasts for about 12 weeks. However, it may be prolonged even up to 6 months especially with carditis or chorea. If rheumatic fever is active for more than 6 months, it can be classified as *chronic rheumatic fever*.

PROPHYLAXIS

Primary Prevention

Antibiotic therapy is effective in eradicating GABHS upper respiratory infection if started within 9 days after onset of symptoms to prevent rheumatic fever, particularly carditis (**Table 6**).

Secondary Prophylaxis

The incidence of recurrence of acute rheumatic fever is more in developing countries and adherence to penicillin prophylaxis is the key against recurrence of acute rheumatic fever and consequent worsening of RHD. Secondary prophylaxis reduces severity and is associated with improvement in heart disease in about 50–70% cases. Secondary prevention is a proven, simple and cost-effective strategy for controlling RHD (**Table 7**). Duration of secondary prophylaxis depends on the presence of carditis during the acute episode: No carditis—prophylaxis for 5 years after last attack or 18 years of age (whichever is longer). Patients with residual heart disease will require lifelong prophylaxis.

Antistreptococcal Vaccine

A GABHS vaccine would prevent acute rheumatic fever and RHD by preventing antecedent GABHS infection. A multivalent M type specific vaccine has completed phase 2 trials in adults with evidence of safety and immunogenicity.

IN A NUTSHELL

1. Acute rheumatic fever is an inflammatory autoimmune disorder that affects several organs of the body characterized by arthritis, carditis, chorea, rheumatic nodules, erythema marginatum and fever caused by GABHS.
2. Peak incidence is between ages 5 and 15 years.
3. Diagnosis is based on Jones criteria and confirmation of streptococcal infection.
4. Carditis is the major cause of morbidity and mortality and is the leading cause of valvular involvement. Mitral and aortic valves are mostly involved.
5. Acute rheumatic fever is treated with aspirin and/or steroids depending on the presence of carditis.
6. Primary prevention consists of appropriate treatment of all episodes of streptococcal sore throat.
7. Children with residual heart disease require lifelong prophylaxis with penicillin.

Chapter 40.30

Rheumatic Heart Disease and Lesions of the Mitral Valve

R Krishna Kumar

Rheumatic heart disease (RHD) is the only long-term sequelae of acute rheumatic fever (RF), a nonsuppurative immune-mediated complication of group A streptococcal pharyngeal infection. RHD, now a rarity in developed nations, still remains a major public health problem in regions with low human development indices.

The mitral valve (MV) is the most frequently affected and maximally damaged structure in children with RHD. In endemic regions with high disease burden, the initial episodes tend to occur at a very young age and are frequently associated with carditis, often severe. Recurrences are common. Advanced heart valve scarring is seen at a young age. Juvenile rheumatic MV stenosis is a well-recognized example that is almost exclusively seen in regions with a high incidence of RF. The involvement of the MV is in the form of either mitral stenosis (MS) or mitral regurgitation (MR) or, not uncommonly, a combination of the two.

A clear understanding of facts and familiarity with all the facets of RF and RHD is still very essential to all pediatricians in India and other developing nations, in spite of a perceptible decline in its incidence. This chapter aims to fulfill the above-mentioned objectives by providing a broad background information regarding basics of rheumatic valvar heart disease with greater focus and emphasis on MV disease.

EPIDEMIOLOGY

Improving living standards, e.g., reduction in overcrowding, improved public hygiene, better access to health care and use of antibiotics for prompt treatment of streptococcal infections in industrialized nations around the world brought about a sharp decline in acute RF and RHD. Interestingly, the decline started even decades before the introduction of penicillin. Industrialized nations now have an average annual RF incidence of less than 0.5 per 100,000 and RHD prevalence of less than 0.05 per 1,000.

In many parts of the developing world, RF and RHD continue unabated like many other infectious diseases, largely reflecting the relatively poor living standards and healthcare availability. The prevalence of RHD in school age children has varied from 0.4 to 21 per 1,000 children in various series from developing countries. RHD being held responsible for one in every 150 deaths and more than 300,000 deaths a year in developing nations remain a major public health burden.

Prevalence estimation of RHD among children has often been done by school surveys in the region, where invariably school enrollment rates were likely to be low. Population-based registries have the potential to capture all age groups, but are heavily dependent on referral mechanisms. Hospital-based statistics selectively report the most seriously affected patients. Recent large studies have used echocardiography in population-based surveys and suggest a much higher prevalence of RHD in children from endemic regions. Most of the cases identified through echocardiography are clinically silent and their natural history is not known at this time. It is also not clear whether penicillin prophylaxis is warranted for clinically silent RHD, although most investigators have chosen to recommend it.

PATHOGENESIS

After an episode of RF with pancarditis, permanent damage is seen affecting only the heart valves whereas all other affected tissues typically heal with no residual sequelae, e.g., complete resolution of other major tissue lesions such as arthritis, chorea, subcutaneous nodules and pericarditis.

The immunopathological findings suggest that RF predominantly damages the vascular endothelium and mesothelium; the adjacent subendothelial and submesothelial tissues get involved to a certain depth. A new endothelium replaces the damaged endothelium within days after injury without significant scarring. The valves are structurally vulnerable for damage in having a small core of connective tissue covered by two layers of endothelium with a predisposition for permanent scarring.

The initial damage in the endothelium is initiated by a humoral immune response, resulting in vascular cell adhesion molecule-1 (VCAM-1) being expressed on the endothelium. Activation of cellular immune response soon follows resulting in attachment of CD4⁺, CD8⁺ T lymphocytes and macrophages to the valvar endothelium and migration to the core of connective tissue. They trigger inflammatory response resulting in neovascularization of the valve substance. The endothelium of the newly formed vessels may serve as a substrate for additional inflammation and perhaps set up a vicious cycle of inflammation, neovascularization and further damage resulting eventually in a permanently scarred valve.

PATHOLOGY

Autopsies of patients dying of RHD revealed that the MV was most commonly afflicted either alone or in combination with aortic valve (AV) and tricuspid valve (TV) (in 31.6% and 52.8% respectively). Organic involvement of the TV was documented in 38.4% of cases. The extent and severity of the disease process was most marked in MV, followed by AV and TV. Involvement of pulmonary valve (PV) is exceptional and is almost always associated with involvement of all valves. MR is the most common lesion encountered in adolescents and children. Other differences in manifestations of RHD between adults and children are listed in **Table 1**.

The well characterized pathologic gross features of RHD from autopsy studies are now well demonstrated through cross sectional [two-dimensional (2-D)] and more recently, through three-dimensional (3-D) echocardiography. **Table 2** lists all the pathologic features of RHD with their echocardiographic correlates.

CLINICAL FEATURES OF RHEUMATIC HEART VALVE DISEASE

A history of acute RF should be diligently sought while evaluating any child with symptoms suggestive of RHD. In many patients with RHD, such a history of episodes of acute RF may not be obtained. Not all episodes of RF may be severe enough to warrant medical attention. Episodes of RF may not be distinguished from other common febrile conditions encountered in childhood especially in the absence of arthritis. The ability of family members to clearly recall a history of RF may also be influenced by their socioeconomic and cultural background. In general, however, families of children who have established RHD at a young age often recall the episode.

A diagnosis of rheumatic carditis requires careful auscultation because murmurs can be subtle during the first episode of RF. Subcutaneous nodules are relatively uncommon and seldom clinically obvious. They need to be searched carefully at specific locations. Erythema marginatum is uncommon, often very

Table 1 Differences between rheumatic heart valve disease in adults versus children

Features	Adults	Children
MV involvement	MS increasingly common as age advances	MR: most common
Mitral stenosis	Varying involvement of valve and the tensor apparatus; calcification seen in older patients	Juvenile form: severe involvement of tensor apparatus with subvalvular fusion
AV involvement	AR and stenosis	AS: distinctly uncommon
Atrial fibrillation	Common in adults with LAE	Uncommon
Left atrial and atrial appendage thrombus	Common especially in presence of atrial fibrillation	Uncommon
Manifestations of PVH	Typical clinical and radiologic features of PVH	Children adapt to high LA pressures through reactive pulmonary vasoconstriction. High LA pressures are better tolerated without substantial activity limitations. Lung signs (clinical examination or X-ray) typically underestimate the severity of PVH
PHT in relation to the severity of PVH	Proportionate increase	Disproportionate increase due to the presence of a significant reactive component

Abbreviations: MV, mitral valve; MS, mitral stenosis; MR, mitral regurgitation; AV, aortic valve; AS, aortic stenosis; AR, aortic regurgitation; LAE, left atrial enlargement; PHT, pulmonary hypertension; PVH, pulmonary venous hypertension; TV, tricuspid valve; PV, pulmonary valve; LA, left atrium.

Table 2 Pathology of rheumatic mitral valve disease and echocardiographic correlates

Mitral valve structures	Pathology	Echocardiographic correlates
AML	Thickening with restriction of mobility of the leaflets especially at the edges resulting in the characteristic diastolic doming	Thickening (> 3–4 mm) identified on echocardiograms, diastolic doming is easily identified on 2-D echocardiography
PML	Fixed to a greater extent by the fibrotic and shortened tendinous chords	Readily identifiable PML with total immobility characteristic a feature of chronic RHD irrespective of whether the dominant lesion is MS or MR
MV commissures in MS	Symmetric fusion of commissures resembling fish mouth	<i>Commissural fusion:</i> Identified in the parasternal short axis view during 2-D echocardiography. Calculation of the stenotic valve area done in this view along the free and fused margins of the leaflets
Tensor apparatus in MS (chords, papillary muscles)	<ul style="list-style-type: none"> • <i>Chords:</i> Thickened and shortened; extensive fibrosis that involves the chords, papillary muscles and the adjacent leaflets responsible for residual MS after balloon dilation of the valve • Rupture of chords may occur during an episode of acute RF resulting in severe MR • Lengthening of the chords has also been described 	<ul style="list-style-type: none"> • <i>2-D/3-D echocardiography:</i> Tensor apparatus well visualized, fibrosis and shortening of the tensor apparatus, reduction in leaflet mobility • Rupture of chords can be identified by examining the free edge of the leaflets. Often the AML is involved

Abbreviations: AML, anterior mitral leaflet; MS, mitral stenosis; MR, mitral regurgitation; MV, mitral valve; PML, posterior mitral leaflet; 2-D, two dimensional; 3-D, three dimensional; RF, rheumatic fever.

transient and cannot be easily seen in dark-skinned individuals. Rheumatic chorea often occurs late after the inciting streptococcal sore throat and is sometimes quite subtle.

The symptoms and physical signs (**Table 3**) of established RHD are related to the severity of the valve affliction and the individual lesions.

Mitral Regurgitation

This is by far the most common lesion seen in RHD. Fatigue is the most common symptom of significant MR and results from the inability of the heart to increase cardiac output effectively to keep pace with the requirements of the body during activity. Palpitations are common in MR because of a volume-loaded hyperdynamic left ventricle and tachycardia. Dyspnea is uncommon unless the MR is severe, acute or the left ventricular myocardium is failing. With failing left ventricle, the left ventricular diastolic pressure increases, the left atrial and pulmonary venous pressure increase and pulmonary congestion appears. Pulmonary arterial hypertension (PAH) follows significant pulmonary venous hypertension (PVH). Some children with chronic severe MR can have disproportionately severe PAH as a result of an exaggerated

vasoconstriction of the pulmonary arterioles. Physical examination is discussed in **Table 3**.

Acute MR results in severe symptoms in the initial stages. This is the direct result of elevation in pulmonary venous mean pressure that results in pulmonary congestion. Over a period of time, the left atrium dilates and becomes more compliant. The LV dilates and accommodates the extra volume and the LV end diastolic pressure declines. A substantial reduction in dyspnea follows. This situation is seen quite frequently following an initial episode of RF with carditis and severe MR. Over a period of time, symptomatic improvement occurs without significant reduction in the degree of MR.

Mitral Stenosis

Rheumatic MS is less frequently seen in children when compared to MR. However, very early onset of MS (juvenile MS) has been described (sometimes as early as 6 years). Juvenile MS is a distinct entity largely confined to parts of the world where RHD is endemic with a very high prevalence. PVH and pulmonary congestion is a direct and predictable consequence of elevated mean left atrial pressure that results from mitral stenosis. Dyspnea

is therefore much commoner than in isolated MR. PAH occurs as a consequence of PVH. The severity of PAH can be variable depending on the degree of *adaptive* pulmonary vasoconstriction. It is not unusual to see children with severe (juvenile) MS with severe pulmonary venous and arterial hypertension who have no apparent discomfort at rest in spite of extremely high pulmonary arterial and left atrial pressures. The severity of symptoms in MS is also critically determined by the duration of diastolic filling period. With tachycardia, diastole shortens to a greater extent than systole. Children with MS are therefore exquisitely sensitive to tachycardia that results from exercise, anxiety and fever and can worsen rather suddenly in the face of these precipitating events. Physical examination is described in **Table 3**.

Combined Valve Lesions (Mitral Regurgitation with Mitral Stenosis)

Combined lesions are frequent in RHD. Typically, MS and MR occur simultaneously. The hemodynamic and clinical consequences are significant because the valve does not open completely in diastole and leaks in systole. Clinical features of both MS and MR can be readily identified in most situations. Multivalve disease involving combinations of MV, AV and TV is common. It is important to precisely quantify the severity of involvement of all the valves to enable correct management decisions. For example, balloon mitral valvotomy (BMV) is precluded in any child with MR that is more than mild and commissural in origin when it occurs with MS. Similarly, the decision on whether or not the aortic valve can be left alone in a patient undergoing mitral valve repair or replacement is dictated by the severity of associated AR.

Chest X-ray in Rheumatic Heart Disease

Cardiac chamber enlargement and changes in lung vasculature may have to be noted. Left atrial and atrial appendage enlargement

almost invariably accompanies significant MV disease. Right atrial enlargement is seen in the context of pulmonary hypertension (PHT) and TV disease. Left ventricular enlargement occurs in the presence of AR and MR. Lungs show varying degrees of pulmonary venous congestion depending on the severity and duration of PVH (**Fig. 1**).

ECG

The ECG (**Fig. 2**) is relatively less sensitive but nonetheless very useful. Left atrial enlargement (LAE) and right ventricular hypertrophy is seen in pure or dominant MS. Left ventricular enlargement with volume overload in the form of q waves in lateral chest leads is seen in MR. Atrial fibrillation as a late consequence of RHD and is unusual in children even in the presence of severe LAE.

Echocardiography

Readily identifiable ECHO specific features in RHD with excellent pathological correlates allow confirmation of RHD (**Table 2**). Simultaneous involvement of multiple valves supports the diagnosis of RHD. The association of MV with AV involvement is infrequent in other conditions. However, there are situations where echocardiographic diagnosis is not straightforward (**Table 4**). It helps to correlate the echocardiographic findings with the clinical context.

The severity of individual lesions can be defined with precision. Gradients across the affected valves can be determined (**Figs 3A to C**) and the severity of regurgitant lesions (**Fig. 4**) can be quantified. The hemodynamic consequences of various lesions can be studied. These include upstream and downstream chamber enlargement, PHT and ventricular function. Serial echocardiography is often used to guide decision regarding timing of surgery. Important complications such as infective endocarditis (IE) can also be readily recognized.

Table 3 Cardiovascular examination in rheumatic mitral valve disease

Physical finding	Mitral stenosis		
	Mild	Moderate	Severe
S ₁	Loud	Louder	Loud/soft in tight MS
S ₂	Normal	S ₂ normal, splitting P ₂ : loud	S ₂ splitting, closer P ₂ : loud
OS	Yes	Earlier occurrence	
A ₂ -OS interval	Wide	Shortens	Shortens further
Other sounds			Systolic ejection click due to PHT
Murmurs	MDM: Relatively soft and late-onset often heard with the bell of the stethoscope, lying down and partially turned to the left lateral position. Murmur may be unmasked by exercise	Prominent MDM with presystolic accentuation	Prominent MDM with presystolic accentuation* Other murmurs: Harsh, ejection systolic murmur, early diastolic murmur of PHT, TR—pansystolic murmur
MDM			
Mitral regurgitation			
Apex beat	Normal apex	Hyperdynamic apex	Cardiac enlargement, downward and outward displaced apex, hyperdynamic precordium
Heart sounds	Normal S ₂ , no S ₃	Widely split S ₂ , S ₃ may be present	Widely split S ₂ (early A ₂), P ₂ may be loud if PHT develops, S ₃
Murmurs	Blowing apical pansystolic, usually not accompanied by a thrill, no flow murmurs. S ₁ merges with the murmur but may be loud and distinct in the presence of accompanying MS	Prominent pansystolic murmur	Frequently a mid-diastolic flow murmur without presystolic accentuation (unless associated with MS)

*Rarely, severe MS may not be associated with an identifiable MDM (silent MS); usually this is accompanied by severe PHT and gross right ventricular enlargement. Abbreviations: OS, opening snap; PHT, pulmonary hypertension; MDM, mid-diastolic murmur; TR, tricuspid regurgitation; MS, mitral stenosis.

Figure 1 Chest X-ray (posterior-anterior view) from a child with juvenile mitral stenosis as a result of rheumatic heart disease. There is evidence of severe pulmonary venous hypertension in the form of prominent upper lobe pulmonary veins (cephalization), interstitial haze and prominent interlobar fissures (arrow). Additionally there is evidence of left atrial (lifting up of the left bronchus) and left atrial appendage (straightening of left heart border)

Echocardiographic Criteria for Established Rheumatic Heart Valve Disease

In some situations, especially when the lesions are mild, there is potential for incorrect labeling. A number of conditions need to be distinguished from rheumatic aortic and MV disease. It is also very important to have clear criteria when large population-based or school surveys of RHD are undertaken. The recently published World Heart Federation echocardiographic criteria allow uniform classification and categorization of RHD. This is particularly useful in clinically silent cases. This includes Doppler criteria and 2-D evidence of morphologic involvement.

SPECIFIC DIAGNOSTIC CHALLENGES

Recurrence of Rheumatic Fever

The challenge is to establish and diagnose active carditis in pre-existing RHD, because the other major criteria may not always be present in recurrent episodes. According to 2002–2003 WHO criteria, a diagnosis of recurrences of RF in the presence of RHD requires the presence at least two minor manifestations of RF plus evidence of preceding group A streptococcal infection [in the form of elevated antistreptolysin O (ASO) titers or a positive throat swab for group A β -hemolytic *Streptococcus*].

Infective Endocarditis

Infective endocarditis can complicate RHD induced regurgitant lesions of MV or AV. IE is rather uncommon in children with isolated MS. An incidence of 2.3% of IE was reported in a large study involving 1,763 RHD patients followed-up over an average period of 5.3 years. The consequences of infective endocarditis are often devastating. Any fever of more than 4–5 days in children with RHD warrants diagnostic work-up for presence of IE as early diagnosis with institution of appropriate antibiotic therapy is vital to limit or minimize further significant valve damage. Three or more blood cultures before administration of antibiotic are mandatory. Other indicators of endocarditis such as microscopic hematuria, leukocytosis, thrombocytopenia and elevations in acute-phase reactants have limited sensitivity and specificity. Echocardiography can identify vegetations on valves affected by RHD. Transesophageal ECHO improves sensitivity substantially, especially in older children.

OUTCOME: LONG-TERM COMPLICATIONS AND NATURAL HISTORY

Severe rheumatic MV disease results in heart failure that is the most common reason for premature death and disability. The key contributors to occurrence of heart failure are PHT, ventricular dysfunction, functional or organic TV involvement, endocarditis and dysrhythmias.

Figure 2 Electrocardiogram from a child with rheumatic heart disease and severe mitral stenosis. There is evidence of right ventricular hypertrophy in the form of rightward deviation of the QRS axis, prominent 'r' waves in V1 and persistent 's' waves in V5 and V6. Additionally there is evidence of left atrial enlargement in the form of prominent broad 'p' waves in lead II

Table 4 Differential diagnosis of rheumatic mitral valve disease from other abnormalities of mitral valve (by age of presentation and ECHO findings)

Condition	Specific differentiating features
Myxomatous mitral valve, MVP	<i>Leaflet mobility:</i> Never restricted; excessive mobility of parts of AML and PML with typically lengthened chordae, MVP typically seen in late systole, associated features include aortic root dilatation. ECHO distinction of chordal rupture in MVP may be challenging from that of acute RF
Isolated cleft in the MV	<i>AML:</i> Usually involved and readily identified by ECHO
Funnel-shaped MV	Fused chordae tendineae with normal papillary muscle arrangement may be confused with Rh.MS, earlier age of onset below 4 years of age unlike that of Rh.MS seen above 6 years of age
MV arcade	Abnormal tensor apparatus near insertion of the papillary muscles onto the valve with resultant severe MR at a very young age
Parachute MV	Readily identifiable single papillary muscle in parasternal short axis view, frequent obstructive lesions at other sites in the left heart (as parts of the Shone complex)
Double orifice MV	Valve tissue between anterior and posterior leaflets
Supramitral membrane	Readily identifiable by ECHO, characteristic origin of the turbulence across the MV at the level of the MV annulus
Inborn errors of metabolic infiltrative diseases of the connective tissue like Hurler's MPS	Early age of onset, dysmorphic features, hepatosplenomegaly, other systemic manifestations
Other inflammatory conditions	Typical absence of fibrotic changes in the MV tensor apparatus characteristically seen in RHD and preservation of leaflet mobility
Anomalous origin of left coronary artery from pulmonary artery (ALCAPA)	Early presentation in infancy, late presentation is rare, specific ECG changes, <i>ECHO:</i> MR may rarely be noted with scarred papillary muscle and relatively preserved LV function; Identifiable origin of the abnormal coronary artery with flow reversal in the left coronary artery

Abbreviations: MVP, mitral valve prolapse; MV, mitral valve; RF, rheumatic fever; MPS, mucopolysaccharidosis; AML, anterior mitral leaflet; PML, posterior mitral leaflet; MR, mitral regurgitation; RHD, rheumatic heart disease; LV, left ventricle.

Pulmonary Hypertension

Pulmonary hypertension frequently complicates RHD. It invariably accompanies severe MS and is frequently associated with severe MR in children. Overall PHT is most common in children in comparison to adults. The reasons for PHT include passive transmission of left atrial and PVH, interstitial edema and reactive pulmonary arteriolar vasoconstriction. PHT is a significant prognostic variable in RHD. It contributes substantially to right heart failure in children with RHD.

Resolution of the PHT has been studied following balloon mitral valvotomy. A part of the PHT that is attributable to passive transmission of elevated pulmonary venous pressure resolves immediately. The reactive component that contributes to elevated pulmonary vascular resistance resolves slowly over weeks to months.

Ventricular Dysfunction

Left ventricular dysfunction is usually the consequence of long-standing and severe MR or AR. The combined presence of severe MR and AR accelerates left ventricular enlargement and dysfunction and contributes to poor long-term outcomes following double valve replacement in children with RHD. Much of the damage appears to result from chronic volume overload; the weight of available evidence does not support a substantial role for myocardial injury during episodes of rheumatic carditis. The natural history of severe MR or AR is not well-characterized in children and this may be somewhat different from adults. Right ventricular dysfunction is a consequence of severe and long-standing PHT.

Infective Endocarditis

Infective endocarditis typically complicates MR or AR and is seldom associated with isolated MS. Endocarditis needs to be suspected in the face of persistent fever or sudden worsening of heart failure.

Dysrhythmias

Unlike in adults, atrial fibrillation is distinctly uncommon in children with RHD even in the face of severe LAE. Atrial fibrillation

has an important influence on the natural history of RHD. Uncontrolled ventricular responses typically herald the onset of atrial fibrillation. The resultant tachycardia often results in marked worsening of symptoms in patients with MS.

Thromboembolism

Severe atrial dilation results in stasis of blood in the left atrium (often visible as spontaneous contrast in echocardiograms) that promotes clot formation. The left atrial appendage (LAA) is the most frequent site for clots to form. Atrial fibrillation greatly increases the propensity for thrombosis. Clots may remain silent and organize in the LAA. However, there is a risk of dislodgement if BMV is attempted in the presence of a clot in the LAA. It is therefore vital to carefully interrogate the LAA through transthoracic and, if needed, transesophageal echocardiography before BMV is contemplated.

Recurrence of Rheumatic Fever

Patients with established RHD are at a particularly high risk of recurrence of RF following an episode of streptococcal sore throat. Recurrences of RF are almost invariably associated with carditis in these patients. Many episodes of RF recurrences are not clinically obvious and this is reflected in the relatively liberal WHO criteria for diagnosis of RF in the presence of RHD.

TREATMENT OF ESTABLISHED RHEUMATIC HEART VALVE DISEASE

Secondary Prophylaxis to Prevent Rheumatic Fever Recurrences

All patients with established RHD must receive secondary prophylaxis. This involves regular administration of penicillin to patients with established RHD, or one or more previous episodes of RF. The success with secondary prophylaxis is critically dependent on patient's education. Drugs, doses and duration of prophylaxis have been discussed in the previous chapter.

Figures 3A to C Two-dimensional echocardiography for rheumatic heart disease and mitral stenosis. The top panel shows a diastolic frame from the parasternal long axis view (A). The characteristic “dog-leg” or “elbow” deformity is shown in the anterior mitral valve leaflet (AML). The tips of the AML are thickened. The thick and shortened chordae attached to the posterior mitral leaflet are also shown in this frame. Frame B is a picture obtained from the parasternal short-axis view. This view captures the mitral valve orifice in mid-diastole and allows accurate estimation of the mitral valve area. This view is also very useful in planning balloon mitral valvotomy (BMV). In this patient, for instance, it can be anticipated that the commissures would split favorably after BMV. The lower panel (C) is a Doppler tracing from the same patient showing the characteristic ‘M’ shaped flow acceleration across the stenotic valve that is seen in patient with MS and sinus rhythm. The second peak results from atrial contraction and is responsible for the presystolic accentuation of the mid-diastolic murmur

Figure 4 Echocardiographic images of severe mitral regurgitation in rheumatic heart disease. The anterior mitral leaflet (AML) is thickened. The tip of the AML is oriented horizontally and does not point downwards suggesting restriction of mobility of diastolic motion. The posterior mitral leaflet (PML) is also thickened and mobility is restricted to even a greater degree. The resultant color Doppler jet is directed posteriorly and laterally

Prophylaxis against Infective Endocarditis

Prophylaxis is no longer necessary unless there is likelihood of breach of oral mucosa, manipulation of either gingival tissue or the periapical region of teeth in presence of valve lesions that are at the highest risk of endocarditis. Thus, routine endocarditis prophylaxis is largely unnecessary for pure MV stenosis. High-risk lesions include the presence of prosthetic valve, AR and MR.

Drug Therapy for Heart Failure

Mitral Stenosis

Diuretics (typically furosemide) provide relief from symptoms of pulmonary congestion. Additionally, it often helps to reduce the heart rate both at rest and following exercise because heart rate reduction translates into an increase in diastolic filling period that helps reduce left atrial pressure. β -blockers have replaced digoxin because of a better efficacy and safety profile. β -blockers may prevent acute worsening of symptoms and occurrence of pulmonary edema and this has been documented in case reports. However, they do not appear to consistently improve exercise capacity in MS patients in sinus rhythm in systematic studies. β -blockers alone or along with a small dose of diuretic can be used in moderate MS and while awaiting BMV or in the event of suboptimal result following the procedure.

Regurgitant Lesions

Symptoms of pulmonary congestion accompanying severe MR or AR are treated mainly with diuretics. The role of systemic vasodilators to reduce systemic afterload in isolated MR and AR is controversial. The most commonly used vasodilators include angiotensin-converting-enzyme inhibitor (ACE) inhibitors and calcium channel blockers. Available data from adult populations do not support the role for administration of systemic afterload reducing agents to delay development of left ventricular dysfunction in MR. An important additional consideration in RHD is the presence of varying degrees of MS that accompanies MR.

In symptomatic patients with isolated severe AR, particularly in the presence of ventricular dysfunction, short-term therapy with vasodilators is perhaps indicated until AV surgery can be performed. In asymptomatic children with severe AR, there is really no evidence that the use of vasodilators have any role in delaying surgery.

Catheter Based Management of Mitral Stenosis

Balloon Mitral Valvotomy

Balloon mitral valvotomy also known as percutaneous trans-septal mitral commissurotomy (PTMC) is now a well-accepted minimally invasive interventional procedure for management of rheumatic MS in children. Improvement in MV area following BMV or PTMC is largely because of splitting of the fused commissures. The contribution of the subvalvar pathology to MS remains after BMV. As a result, MV area does not normalize after BMV.

The most popular dilatation of stenosed MV by BMV employs the Inoue balloon. The key initial step involves puncture of the interatrial septum with the Brockenbrough needle. The immediate results of BMV in children are comparable to adults. In a large series of 81 patients with juvenile MS, Bahl et al. demonstrated an increase in valve area by $172 \pm 62\%$ (from a mean of $0.8 \pm 0.4 \text{ cm}^2$ to $2.2 \pm 0.5 \text{ cm}^2$). The potential risk of BMV is occurrence of MR. With careful case selection, severe MR is rare.

Valve pathology is an important determinant of immediate and long-term outcome. Echocardiography allows assessment of a number of variables that can help predict the results of BMV both in terms of improvement in valve area and reduction in gradients and occurrence of significant MR. These variables include nature of commissural fusion, severity of subvalvar deformity, leaflet mobility and calcification. Trivial MR via the central valve orifice does not progress or may even disappear following BMV. However, MR at the commissures may progress following BMV.

Long-term follow-up after BMV is mandatory as there is a significant risk of restenosis with time. Restenosis is typically associated with significant residual MS (typically because of subvalvar pathology) following BMV. Repeat BMV is an option for restenosis and helps postpone open MV surgery.

Surgery

- **Rheumatic MS** Closed or open mitral commissurotomy is an effective surgical procedure that has been replaced by BMV.
- **Rheumatic MR** Repair of the MV should be considered whenever feasible as it is reported to offer excellent immediate and acceptable intermediate term outcomes. However, the results of MV repair in RHD with MR are not as consistently reproducible as they are for MR associated with myxomatous disease.
- **MR with MS** It is particularly difficult to deal with.

Additionally, there are major long-term concerns with RHD. There is evidence that the inflammation in chronic RHD continues well beyond the initial episode of RF and this may result in continuing injury to the heart valve and tensor apparatus after *successful* repair. There are several other challenges. Repeated operations are unrealistic in most environments where RHD is prevalent because

of the expense involved with open heart surgery. It is, however, equally important to recognize the limitations of MV replacement with a mechanical prosthetic valve in younger patients.

Monitoring anticoagulation is particularly challenging in most parts of the developing world. Pregnancy imposes a substantial additional risk in females. The surgical approach to RHD with MR needs to be individualized based on the valve pathology, gender, age, resources, surgical expertise, patient and family preference.

There are no clear guidelines for the timing of MV surgery (particularly replacement) in children. Persistent symptoms in spite of maximally tolerated medications warrant consideration of surgery especially in the face of pulmonary artery hypertension. For asymptomatic patients, any evidence of ventricular dysfunction clearly merits consideration for surgery. Standard guidelines for MV surgery in adults do not apply to children. The natural history of chronic valve regurgitation appears to be quite different in children when compared to adults. There is an urgent need to perform good prospective studies to study the natural history of MR in children.

For patients with RHD with combined mitral and AV disease, the threshold for replacing both valves is quite high in most environments. This is because of expense and morbidity and concerns regarding long-term outcome in the face of erratic anticoagulation. Many surgeons, therefore, choose to replace the valve that is severely affected (typically the mitral valve) and leave the less severely affected valve alone (often the aortic valve). It has been shown that the mild or moderate AV disease does not progress rapidly over several years after MV replacement for RHD.

Associated TV disease can be repaired in most instances. In almost all cases the mitral, aortic or both are affected. Typically, annuloplasty of the dilated TV annulus is sufficient to restore competence.

IN A NUTSHELL

1. MV is the most common valve involved in RHD in children with MR being the commonest lesion. Early-onset MS is largely limited to regions with high RHD prevalence.
2. A variety of conditions need to be considered in the differential diagnosis. Most common conditions include MV prolapse in association with myxomatous degeneration and congenital MV disease.
3. Advanced untreated RHD with MV disease is associated with premature death and morbidity from a variety of complications that include heart failure and endocarditis.
4. Medical management includes secondary penicillin prophylaxis and diuretics. β -blockers are useful in MS and vasodilators may be considered for MR.
5. Surgical management involves MV repair and replacement. Repair should be considered in isolated MR but requires an experienced and committed surgeon.
6. BMV is a useful option for isolated MS providing relief for many years.

Chapter 40.31

Rheumatic Aortic Valve Disease

Savitri Shrivastava

Aortic valve involvement in rheumatic fever with carditis is not uncommon in developing nations. The aortic valve may be involved in the acute phase of illness, i.e., active carditis or later in the form of chronic valvar heart disease. Rheumatic carditis results in annular nodular thickening resulting in lack of coaptation and prolapse of the aortic valve, retraction of the aortic valve and annular dilatation.

In patients of acute rheumatic fever, the most common valvar lesion is mitral regurgitation which may be associated with aortic regurgitation (AR). Presentation with significant AR in acute phase of rheumatic fever is very rare. With first attack of rheumatic carditis, mild to moderate degree of echocardiographically demonstrated AR is reported to occur between 5% and 25% of children, but isolated AR is seen in less than 2–8% of cases. However, AR with mitral valve disease is much more common. The AR murmur is classically an early diastolic high-pitched decrescendo murmur after the second component of second heart sound. The management in the acute phase is like management of active rheumatic carditis, as discussed earlier.

AORTIC REGURGITATION

Aortic valve involvement in rheumatic heart disease (RHD) results in AR. Rheumatic aortic stenosis (AS) has never been described in literature in pediatric age group. Rheumatic involvement of the aortic valve results in distortion and retraction of the aortic cusps, which leads to noncoaptation of the cusps resulting in AR, the mitral valve is histologically always involved in the rheumatic process. Clinically, isolated AR, without associated clinical mitral valve disease, is rare and occurs in only 2–8% of patients with rheumatic fever and RHD, but AR with mitral valve disease either regurgitation or stenosis is much more common, seen in approximately 40% of cases.

HEMODYNAMICS

Aortic regurgitation is a backward leak from the aorta into the left ventricle (LV) during diastole. This increases the volume of blood reaching the LV which increases in size to accommodate the extra regurgitant volume from aortic run off. The LV size is thus directly related to the degree of aortic leak unless there is myocardial dysfunction. This increased LV volume results in palpitation, because of the backward flow of blood the forward flow is compensated by peripheral vasodilatation as well as increased ejection from the LV during early part of the systole. However, significant AR results in low forward output during exercise. The pulse pressure is wide because of increased systolic and lowered diastolic pressure. Signs of wide pulse pressure in the form of exaggerated arterial and arteriolar pulsations are invariably present except in mild AR or AR in failure. Slowing of heart rate increases the diastolic period and increases the regurgitant volume of blood in AR. With good left ventricular myocardial function even moderate AR is tolerated well for long periods, one-fourth of the patients of isolated AR can develop significant left ventricular dysfunction in later stages with the onset of left ventricular decompensation. With the failing myocardium, the left ventricular diastolic pressure rises and results in an increase in left atrial pressure and pulmonary venous hypertension which results in exertional dyspnea and audible third heart sound (S_3) and rarely fourth heart sound (S_4)

In later stages, the pulmonary arterial pressure may also rise resulting in loud pulmonary component of the second heart sound (S_2).

Significant LV dilatation is accompanied with abnormal stress on the mitral valve-papillary muscle complex. This may result in inadequate apposition of the mitral leaflets and appearance of mitral regurgitation.

CLINICAL FEATURES

Aortic regurgitation of mild to moderate degree is often well tolerated. The forward flow can be raised effectively on exercise. So, fatigue is not an early symptom. The large stroke volume and forceful left ventricular contractions results in palpitations which is the earliest symptom in patient of AR. Peripheral vasodilatation results in excessive sweating and heat intolerance. In severe AR with failing LV, dyspnea on effort occurs which can progress to orthopnea and to overt signs of pulmonary edema if not appropriately treated. Signs of AR are as follows:

- The pulse pressure is wide. The wider the pulse pressure, the more severe is the aortic leak.
- Prominent carotid pulsations (*Corrigan's sign*), visible arterial pulsations over the extremity vessels (*dancing peripheral arteries*) and visible pulsations of the abdominal aorta can be seen. These are signs of wide pulse pressure and can be seen in all other conditions which results in aortic run off.
- On holding the middle of the forearm or leg and elevating it a sharply rising and abruptly falling pulse wave can be felt. (*Corrigan's pulse* or *water-hammer pulse*).
- Nodding of the head may be present with each systole (*de Musset's sign*) due to sudden filling of the carotid vessels in severe AR.
- Arteriolar pulsations may be seen over the nail bed, uvula, lips, earlobes and in the eyes.
- *Hill's sign*: There is exaggeration of the systolic pressure difference between the brachial and femoral arteries. Normally, the difference between the systolic pressure in the brachial artery and the femoral artery is less than 20 mm Hg, the femoral systolic pressure being higher. Systolic pressure difference between 20 mm Hg and 40 mm Hg suggests mild AR. If the difference is between 40 mm Hg and 60 mm Hg, it suggests moderate AR. A difference of more than 60 mm Hg indicates severe AR.
- *Pistol shot sounds*: If the stethoscope is put over the brachial or the femoral artery without applying any pressure *pistol shot sounds* may be heard in moderate and severe AR.
- *Duroziez's sign*: A systolic murmur may be heard if pressure is applied to partially occlude the artery proximal to the chest piece of the stethoscope and a diastolic murmur will be heard if pressure is applied distally. This combination of systolic and diastolic murmurs is called *Duroziez's sign*.
- *Cardiac examination*:
 - Cardiomegaly is present with significant AR. The apex is displaced downward and outward, the degree of cardiac enlargement depends upon the severity of AR. The apex beat is ill-sustained LV type typical for left ventricular volume overload.
 - With severe AR, the whole chest wall may show a to and fro movement. Uncommonly, a diastolic thrill may be palpable at the upper left or right sternal border.
 - The first sound (S_1) is soft and the aortic component of the S_2 may be audible or may be masked by the regurgitant diastolic murmur. The split of the S_2 is normal with mild to moderate AR and with severe AR it may be single on paradoxically split particularly if left ventricular failure has set in.

Figure 1 Electrocardiogram showing high voltages on left ventricular leads and tall T waves in a patient with significant aortic regurgitation

- The AR murmur is a high pitched blowing, decrescendo diastolic murmur starting with the aortic component of the S_2 . The length of the diastolic murmur depends on AR severity. With severe AR, it is pandsystolic. The murmur is best heard along the left sternal border mostly but may be heard at right sternal boarder. It radiates to the apex and even beyond the apex. The murmur is best heard with the diaphragm of stethoscope, withheld expiration and patient in leaning forward position.
- With large aortic leaks, there is also an ejection systolic murmur at the second right intercostal space conducted to the neck and not infrequently associated with a systolic thrill. The systolic murmur is the result of a large stroke volume passing across rough valve. It does not indicate AS if the pulse pressure is wide and the carotid upstroke is brisk.
- S_3 may be audible with significant AR and in patients with congestive heart failure. Rarely, if the left ventricular end diastolic pressure is severely elevated a left ventricular S_4 may be heard.
- Delayed diastolic rumbling murmur may be heard in late phase of diastole at the apex named Austin Flint murmur. The backward jet of AR hits the anterior mitral leaflet (AML) and mitral inflow, setting the AML in a flutter, well appreciated in M-mode echocardiography. Sometimes, this murmur may be confused with mitral stenosis murmur but loud S_1 , opening snap and presystolic accentuation of the mitral diastolic murmur is hallmark of mitral stenosis in patients with isolated AR.
- Signs of congestive heart failure are apparent in patients with failing left ventricle.

ELECTROCARDIOGRAM (FIG. 1)

Electrocardiogram (ECG) may be normal with mild AR, but with significant AR there will be signs of left ventricular volume overload. There are deep Q waves with increased left ventricular voltage in left sided chest leads accompanied with tall T waves. The pattern of deep Q waves and tall T waves has been called the diastolic overloading pattern of the LV. With onset on left ventricular failure, ST and T changes over left ventricular leads develop.

CHEST ROENTGENOGRAM (FIG. 2)

Cardiac enlargement of the left ventricular type with dilated aorta is seen in significant AR. There may be evidence of pulmonary

Figure 2 Chest X-ray showing cardiomegaly left ventricular type and prominent aorta in a patient with moderate aortic regurgitation

venous and arterial hypertension with severe AR and myocardial dysfunction.

TWO-DIMENSIONAL ECHOCARDIOGRAPHY WITH COLOR FLOW MAPPING (FIGS 3 TO 5)

Echocardiogram (ECHO) is an extremely useful modality in evaluating AR in children with RF and RHD. The 2-D profilation clearly shows the morphology of the aortic valve which helps in the diagnosis and also assessment of the reparability of the valve. The aortic root dimension and left ventricular size can be measured. If the left ventricular size is greater than or equal to 25 mm/m^2 or if there is progressive increase in left ventricular size, the surgical option has to be considered. The left ventricular diastolic as well as systolic function can be assessed. At the earliest indication of functional impairment surgery is the treatment of choice. On color flow mapping, the quantum of AR can be estimated by size of color flow regurgitation jet and the area occupied by the regurgitant blood in relation to the left ventricular cavity.

DIFFERENTIAL DIAGNOSIS

- *Conditions associated with a wide pulse pressure:* Patent ductus arteriosus, ventricular septal defect with AR, ruptured sinus

Figure 3 2-D echocardiogram (long axis view) showing dilated left ventricle (LV) and aorta (AO)

Figure 5 2-D echocardiogram with color flow mapping (long axis view) showing turbulent jet of moderate aortic regurgitation
Abbreviations: LV, left ventricle; Ao, aorta; RA, right atrium; LA, left atrium.

of Valsalva, arteriovenous fistulae—coronary or peripheral, anemia and thyrotoxicosis.

- *Conditions associated with a nonrheumatic AR:* Prolapse of aortic sinus with ventricular septal defect and AR, congenital aortic valve disease, Marfan syndrome, Hurler syndrome and idiopathic obstructive aortoarteritis.
- Conditions associated with basal early diastolic murmur of pulmonary regurgitation.

MANAGEMENT

Mild to moderate AR is known to be well tolerated for years with proper RF prophylaxis. Digitalis, though conventionally used to treat congestive cardiac failure (CHF) in RHD children; however, it is known to increase the regurgitant volume of blood by slowing the heart rate. Vasodilators, especially angiotensin-converting enzyme inhibitors are helpful as first line in severe CHF to tide over the acute condition before operation and should be the mainstay of management. If there is pulmonary venous hypertension and right-sided failure, diuretics and salt restriction should also be advised. Penicillin prophylaxis should be continued.

Figure 4 2-D echocardiogram (apical four-chamber view) showing enlarged left ventricle (LV), right atrium (RA), left atrium (LA) and right ventricle (RV)

In patients with significant AR with left ventricular end-diastolic dimension of greater than or equal to 25 mm/m², the patient will need aortic valve replacement. Aortic valve repair is mostly not possible as the aortic leaflets are markedly deformed. Ross procedure in which autograft, i.e., pulmonary valve of the patient is implanted in aortic position and homograft or a valved conduit is placed in pulmonary position can be performed. But Ross procedure has not shown promise in rheumatic AR. The only option left is prosthetic aortic valve replacement. The long-term results are good. The only problem is that lifelong anticoagulation and surveillance is needed. Timely surgery prevents development of ventricular dysfunction, pulmonary hypertension and arrhythmias.

Before a pediatric patient is sent up for valve replacement surgery, one should consider and treat effectively before undertaking re-evaluation of cardiac function and surgery: (a) presence of rheumatic activity since active carditis by itself can cause cardiac enlargement and (b) any anemia contributing to cardiac enlargement and symptoms.

IN A NUTSHELL

1. Aortic valve involvement in RHD results in AR.
2. Rheumatic AS has never been described in literature in pediatric age group.
3. Rheumatic involvement of the aortic valve results in distortion and retraction of the aortic cusps which leads to noncoaptation of the cusps resulting in AR; the mitral valve is histologically always involved in the rheumatic process.
4. Clinically isolated AR—without associated clinical mitral valve disease—is rare and occurs in only 2–8% of patients with rheumatic fever and RHD, but AR with mitral valve disease either regurgitation or stenosis is much more common, seen in approximately 40% of cases.
5. Palpitation is the earliest symptom in patient of AR. Examination reveals signs of peripheral runoff including a wide pulse pressure.
6. The AR murmur is a high pitched blowing, decrescendo diastolic murmur starting with the aortic component of the S₂.
7. Vasodilators, especially angiotensin-converting enzyme inhibitors are helpful as first-line drugs for treating heart failure in AR.

Chapter 40.32

Takayasu Arteritis

Biswajit Bandyopadhyay

Takayasu arteritis is a chronic inflammatory disease of the aorta and its major branches. The disorder is a large vessel vasculitis (often granulomatous) of unknown origin that has been reported in pediatric patients as young as age 6 months and in adults of every age. In children, Takayasu arteritis is one of the more common etiologies of renovascular hypertension. Despite the term pulseless disease, which is a synonym for Takayasu arteritis, the predominant finding in individuals with Takayasu arteritis is asymmetrical pulse. Absent peripheral pulses occur late in the course of the disease. Although 5-year survival rates exceed 90%, the disease has a high incidence of residual morbidity.

ETIOLOGY

Takayasu arteritis is common in developing countries, where the disease is closely associated with tuberculosis. The nature of this association is unclear because most patients with Takayasu arteritis in the United States do not have tuberculosis. Spirochetes, streptococcal organisms and circulating antibodies due to an autoimmune process are also implicated. In endemic areas, active tuberculosis may perpetuate Takayasu disease activity through molecular mimicry or chronic antigen stimulation. Girls are twice as commonly affected as boys. Genetic factors may play a role in the pathogenesis.

PATHOPHYSIOLOGY

The clinical course of Takayasu arteritis is characterized by two often overlapping phases: (i) the acute, active inflammatory prepulseless phase and (ii) the chronic pulseless end-stage phase. During the acute, active prepulseless phase, histologic study demonstrates a granulomatous arteritis involving all layers of the artery, particularly the media. Characteristic changes of the pulseless end-stage phase of the disease include progressive intimal and adventitial fibrosis and extensive scarring and degeneration of the media changes associated with progressive segmental arterial stenosis, occlusion, dilation and aneurysm formation. Stenoses are the most common lesion, found in 90% of patients with Takayasu arteritis. Patients often have poststenotic dilatations and other aneurysmal areas, reported up to 45%. Endothelial activation leads to a hypercoagulable state predisposing the patient to thrombosis. Congestive heart failure in individuals with Takayasu arteritis may occur as a result of hypertension, aortic root dilation or myocarditis.

Human studies suggesting endothelial cell activation have demonstrated increased expression of intercellular adhesion molecule-1 (ICAM-1) and vascular cell adhesion molecule-1 (VCAM-1) in patients with Takayasu arteritis. Evidence for an autoimmune etiology is supported by circulating antiaortic antibodies and antiendothelial cell antibodies found in the sera of patients with Takayasu arteritis. Immunoglobulin G (IgG), IgM and properdin deposits are found in lesions from pathologic specimens. Autoreactive T-cells, Th1 and Th17, are increased in active Takayasu arteritis along with decreased numbers of FOXP3-positive Treg cells.

Cytokine abnormalities include elevated tumor necrosis factor and interleukin (IL)-6. More recently, B-cells are identified as contributing to Takayasu arteritis with plasmablast expansion

in patients with active Takayasu arteritis. This increase in B-cells is not seen in inactive disease. IL-6 and B-cell activating factor (BAFF) also increase total numbers of circulating B-cells; reduction in disease activity is observed with successful depletion of B-cells with anti-CD20 and increase in B-cells observed with relapse.

CLINICAL FEATURES

Prepulseless Phase

Manifestations during the active inflammatory *prepulseless phase* include constitutional symptoms, intermittent nausea and vomiting, abdominal pain, arthralgia/arthritis, myalgia, cough, hemoptysis, pleuritis, transient skin nodules, transient episcleritis, headache, neurologic deficits, lymphadenopathy, anemia and elevated sedimentation rate. The peripheral pulses and blood pressures may be normal, making diagnosis difficult. Aortography may only demonstrate nonspecific thickening of the vessel wall.

Pulseless Phase

As the disease progresses into the chronic pulseless phase, additional symptoms and signs that make the diagnosis more obvious include extremity claudication, particularly in the arm; bruits over the cervical, supraclavicular and abdominal regions; absent or decreased brachial and radial pulses; a systolic blood pressure difference greater than 10 mm Hg between arms; decreased femoral pulses; aortic incompetence; hypertension; congestive heart failure; angina (from rare coronary artery involvement); hemiplegia; seizures; syncopal episodes and fundoscopic abnormalities, including the wreathlike anastomosis surrounding the optic disc, as originally described by Takayasu.

DIAGNOSIS

Acute phase reactants are elevated with leukocytosis and thrombocytosis. Erythrocyte sedimentation rate (ESR), transaminases and von Willebrand factor-related antigen are elevated. Antiendothelial antibodies are present. Antinuclear antibody results are usually negative. Rheumatoid factor is elevated in 15%. The biomarker pentraxin 3, a protein closely related to C-reactive protein, may be positive in some patients with active disease with a normal C-reactive protein. Matrix metalloproteinase (MMP)-9 is also synthesized and is elevated in active disease.

Determining Disease Activity

It is a major challenge because of poor correlation among clinical, laboratory, radiologic and histologic data. 18F-fluorodeoxyglucose positron emission tomography (FDG-PET) has been evaluated in the assessment of disease activity; preliminary results were encouraging, showing high sensitivity and specificity for the presence of inflammation. However, the clinical usefulness of this test remains uncertain and its correlation with disease activity has been questioned.

Imaging Studies

During the chronic pulseless phase, chest radiography may show cardiomegaly, decreased pulmonary vascular markings, irregular contour of the descending aorta, dilation of the aortic arch and linear calcification of the aortic wall. Duplex color flow Doppler ultrasonography may reveal mural thickening and turbulent flow in the carotid arteries and abdominal aorta, stenosis and poststenotic dilation in the abdominal aorta, stenosis or occlusion of subclavian arteries and distal dampened

monophasic flow in the brachial arteries. Echocardiography can detect aortic root dilation, coronary artery involvement and the aortic and mitral valve regurgitation associated with Takayasu arteritis. MRI may reveal narrowing and occlusion of large arteries. Conventional thoracic and abdominal aortography provides the most complete and accurate assessment of the aorta and its major branches. Angiographic findings include stenosis (**Fig. 1**), occlusion, dilation and aneurysm formation in the aorta, its major branches and the pulmonary artery, and demonstration of collateral circulation. In children, the most commonly involved arteries in descending order are the abdominal aorta and renal arteries, thoracic aorta, subclavian artery, carotid artery and pulmonary artery. Less commonly involved are the superior mesenteric, celiac, vertebral, hepatic and coronary arteries.

TREATMENT

Pharmacological Management

During the active inflammatory prepulseless phase of the disease, the patient should be treated with prednisone, 1–2 mg/kg/day for approximately 1 month, followed by slow tapering over several months. However, although 60% of patients respond to this treatment, 40% relapse on steroid taper. Patients not responding to corticosteroids or who relapse during corticosteroid taper require an additional agent. Symptoms of patients who relapse on corticosteroid taper may be controlled with weekly infusions of methylprednisolone (30 mg/kg, not to exceed 1 g/week). However, extensive use of these infusions is associated with significant steroid-induced toxicity if continued for any significant period. Methotrexate, infliximab, etanercept, cyclosporine, cyclophosphamide and mycophenolate mofetil also allow disease control and weaning from steroids.

The presence of antiendothelial antibodies and plasmablast expansion in patients with active Takayasu arteritis suggest a role for B-cell based therapies. Reports using rituximab, monoclonal anti-CD20 antibody and tocilizumab (monoclonal anti-IL-6-receptor antibody) have described remission induction in Takayasu arteritis resistant to other treatments. Anecdotal reports of matrix metalloproteinase inhibition using minocycline suggest that this may be a useful adjunctive therapy which may also allow lower doses of corticosteroids, and thus reduced toxicity.

Figure 1 Nonsurgical interventions

Surgical Management

Whenever feasible, anatomic correction of clinically significant lesions should be considered, especially in the setting of renal artery stenosis and hypertension. Severe or progressive changes may require aortic surgery with or without valve replacement. Because of the high prevalence of subclavian and carotid stenoses in Takayasu arteritis, severe symptomatic stenoses of these vessels should be treated by grafts that originate from the aortic root and not from an arch vessel to another arch vessel. The latter may be followed by loss of the graft because of new stenosis in an initially spared subclavian or carotid artery. Conversely, a graft from the ascending aorta is a safer long-term conduit because the ascending aorta in Takayasu arteritis essentially never becomes stenotic. Mesenteric and celiac artery stenoses are usually asymptomatic and only rarely require surgery. Angioplasty and intravascular stents have met with restenosis far more often than bypass, which is preferred whenever feasible.

It is always best to operate on patients who are in remission; however, judgment of disease activity in Takayasu arteritis may be difficult. Consequently, all bypass surgeries should include vascular biopsy specimens for histopathologic evaluation. Findings from surgical specimens may help guide the need for postoperative immunosuppressive treatment.

Nonsurgical Interventions

Takayasu's arteritis is a chronic granulomatous arteritis that affects the large vessels with predilection to aorta and its branches. Chronic inflammation leads to stenosis of the involved vessels and rarely aneurysms. With the advent of percutaneous transluminal angioplasty (PTA), most of the large vessel stenosis can be treated without surgical intervention with or without stent placement. The uses include PTA with stenting of renal arteries thus treating the hypertension due to renal artery stenosis; the cerebral arteries thus preventing a cerebrovascular event; celiac and mesenteric arteries thus preventing mesenteric ischemia, subclavian and iliac arteries thus preventing limb claudication.

PROGNOSIS

More than half of patients with Takayasu arteritis achieve control on corticosteroids alone; however, their relapse rate is high and they require long periods of steroid treatment. Morbidities are related to ischemia and hypertension and include congestive heart failure, transient ischemic attacks, stroke and visual disturbances. Chronic, low-grade dissection of the aorta may cause recurrent chest pain for years. Upon autopsy, children with Takayasu arteritis who have died from acute rupture of the aorta have often been found to have evidence of multiple small dissections that did not progress. Survival rate at 15 years is as high as 95%.

Chapter 40.33

Congestive Heart Failure

Parvathi U Iyer, Harsheen Kaur, Neeraj Awasthy

In the current era, heart failure (HF) has attained epidemic proportions in adults. So, there has been tremendous strides in the understanding of the pathophysiology and management strategies of HF in adults. Recently in 2013, the American College of Cardiology Foundation (ACCF) and American Heart Association (AHA) issued the *ACCF/AHA Guideline for the Management of Heart Failure: Executive Summary* which provides excellent clinical practice guidelines for the management of acute and chronic heart failure in adults. Unfortunately, such clear cut clinical practice guidelines are not available for pediatrics population.

Heart failure in infants and children is becoming an increasingly important cause of hospital admissions globally. The last two decades have witnessed huge advances in the field of pediatric cardiology and cardiac surgery with recourse to aggressive cardiac catheter interventions and complex cardiac surgery in infants and small children. These advances have led to increasing survival of complex and palliated cardiac disease and have generated a large and ever increasing pool of children and adolescents with HF. Pediatric HF thus poses an ever increasing economic, social and psychological burden on parents and the extended family due to the current trend of greater recourse to cardiac catheter interventions and palliative cardiac surgeries. So, though the prevalence of pediatric HF is less as compared to adults the overall impact of pediatric HF is still considerable and is expected to increase with time.

DEFINITION

Heart failure is a clinical syndrome characterized by the inability of the heart to supply cardiac output to meet the metabolic demands of the body. In case of infants, this requirement includes appropriate *growth and development*. Congestive heart failure can be divided into a low cardiac output and a normal cardiac output state.

Low output state is defined as *the inability to supply sufficient cardiac output to keep up with metabolic demands of the body*.

Normal output state is defined as *an ability to supply sufficient cardiac output but with elevated ventricular filling pressures*.

A child is said to be in *cardiogenic shock* if tissue perfusion is compromised secondary to pump failure or due to the low cardiac output state.

CLASSIFICATION

The traditional New York Heart Association (NYHA) classification of HF is not applicable to infants and small children. The Ross classification of HF was developed for HF assessment in infants and the modified Ross classification incorporated relevant issues like feeding difficulty and growth failure into a severity index (**Table 1**). The more recently developed New York University Pediatric Heart Failure index uses physiologic parameters to generate a severity based weighted score ranging from 0 (no HF) to 30 (severe HF). None of these are perfect scoring systems and have not been validated adequately in large numbers of children with congenital heart disease.

ETIOLOGY

Heart failure in pediatric population is mostly due to untreated or treated congenital heart disease, acute myocarditis or various forms of cardiomyopathy. In our country, acute and chronic rheumatic

Table 1 Modified Ross heart failure classification for children

Class I	Asymptomatic
Class II	Mild tachypnea or diaphoresis with feeding in infants Dyspnea on exertion in older children
Class III	Marked tachypnea or diaphoresis with feeding in infants Marked dyspnea on exertion Prolonged feeding times with growth failure
Class IV	Symptoms such as tachypnea, retractions, grunting, or diaphoresis at rest

heart disease continues to be an important cause of childhood and adolescent HF. In some parts of India, severe anemia, malaria, malnutrition, vitamin deficiencies, hypocalcemia and vitamin D deficiency are important, often missed but easily treatable causes of infant and childhood HF. This is in contrast to adults in whom coronary artery disease, hypertension and sometimes rheumatic and congenital valvar heart disease are the main causes of HF. Today, surgically treated congenital heart disease (operated tetralogy of Fallot [TOF] who develop pulmonary regurgitation in later life, Fontan operation for tricuspid atresia and other single ventricle situations) have become increasingly important causes of HF in young adults.

Important triggering factors of HF especially in emerging economies like India include acute anemia, rheumatic activity, infective endocarditis, intercurrent infections, electrolyte imbalances (hypocalcemia) and fluid overload. Other triggers of acute HF are arrhythmias (tachycardiomyopathy or bradyarrhythmias) arising de novo or after surgery for congenital or acquired heart disease (in the early postoperative period or late onset arrhythmias).

The most common cause of HF in infancy is due to left ventricular volume loading and pulmonary overcirculation due to large left to right shunts—isolated ventricular septal defects or in combination with large atrial septal defects or patent ductus arteriosus (PDA). On the other hand the most frequent cause of HF in older children and adolescents is regurgitant lesions—mitral and or aortic regurgitation or pulmonary regurgitation in late postoperative TOF. Pressure overload due to obstructive lesions (e.g., aortic valvar stenosis) causes an increase in ventricular afterload which finally leads to increased wall stress and myocardial hypertrophy decreasing the left ventricle (LV)/right ventricle (RV) cavity size. The cardiac output decreases, causing myocardial ischemia. In the neonatal period, babies with obstructive lesions (critical aortic stenosis, coarctation of aorta, aortic arch interruption) may rapidly develop HF, deteriorate swiftly and present in circulatory collapse.

At any rate, it is of paramount importance to exclude *structural heart disease* in pediatric HF since the majority can be either corrected or palliated today. Once structural heart disease has been reasonably excluded the causes of HF include intrinsic myocardial disease—myocarditis, cardiomyopathy, toxic, metabolic or infiltrative myocardial conditions. Sepsis is increasingly recognized to directly impact myocardial pump function adversely and cause HF. **Table 2** enumerates usual causes of pediatric HF and **Table 3** describes the causes of HF in neonates.

PATHOPHYSIOLOGY

Heart failure occurs due to either intrinsic myocardial factors or extrinsic pericardial factors. Extrinsic factors act by impeding venous return to the heart leading to a low cardiac output state. Extrinsic causes include acute and chronic constrictive pericarditis pericardial effusions and sometimes large pleural collections or large pneumothorax.

Table 2 Causes of pediatric heart failure (HF)

A. Structural lesions	
I. Congenital defects	
1. Volume overload	
a. Left to right (L-R) shunts

5. Severe malnutrition, vitamin deficiency	
6. Arrhythmias	
7. Burns	
8. Infectious	
9. Toxic (diphtheria)	
III. Miscellaneous (highly relevant today)	
After heart surgery: Postcardiopulmonary bypass ventricular dysfunction	

Heart failure (HF) due to intrinsic *myocardial pump failure* occurs due to ventricular systolic, diastolic dysfunction or abnormal ventriculoarterial coupling, i.e., an exaggerated, inappropriate or abnormal afterload on a normal myocardium. Congenital or acquired defects causing right or left ventricular volume loading

Table 3 Causes of neonatal heart failure (HF)

Neonatal cardiac failure → Untreated → Shock	
<ul style="list-style-type: none"> • Obstructive left-sided cardiac lesions <ul style="list-style-type: none"> – Aortic stenosis – Hypoplastic left heart syndrome – Coarctation of the aorta – Interrupted aortic arch • Late presentation of <i>duct dependent</i> defects 	

lead to ventricular dilatation which is finally associated with *systolic dysfunction* or impaired myocardial pumping. Similarly congenital or acquired defects causing right or left ventricular pressure overload lead to ventricular hypertrophy which is associated with *diastolic dysfunction*. Diastolic dysfunction often referred to as *restrictive physiology* is a situation where there is increased resistance to left or right ventricular filling due to *stiff or noncompliant* ventricles giving rise to symptoms of congestion. It is important to recognize scenarios of predominant diastolic dysfunction since inotropes may worsen diastolic dysfunction. Inotropes are far more effective in primarily systolic dysfunction. The normal neonate has a restrictive physiology and exemplifies left ventricular diastolic dysfunction. Examples of right ventricular diastolic dysfunction include unoperated and operated TOF. Restrictive forms of cardiomyopathy is also an example of diastolic dysfunction. Not infrequently systolic and diastolic dysfunction coexist and HF management can then be challenging.

Why does Myocardial Pump Failure Occur?

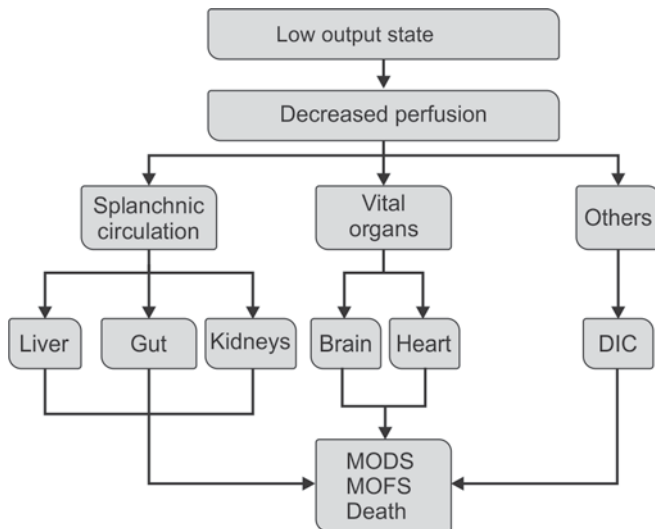

The cause of myocyte dysfunction is today thought to be multifactorial in etiology. There is increasing evidence that neurohumoral imbalance and an ionopathy with sodium and calcium dysregulation occur in HF. Reduced calcium has been shown to affect both systolic and diastolic performance. Inflammatory processes with increase in tumor necrosis factor α , interleukin-1 and actin disruption have all been shown to occur in pediatric HF. It is important to be aware of these advances since they have tremendous implications in current day management of HF.

Effect of Heart Failure

Heart failure if untreated goes on to develop diminishing cardiac output resulting finally in end-organ dysfunction, failure and death (**Flow chart 1**). In the presence of HF, i.e., whenever the heart cannot meet the requirements of the body at normal physiological filling pressures a number of *short-term adaptive* responses occur. These may be considered as a *hemodynamic defense response* aimed at improving myocardial systolic, diastolic function, overall myocardial performance and thereby increasing cardiac output. These responses occur through the release of a host of intrinsic humoral mediators which include epinephrine, norepinephrine, angiotensin II, aldosterone, arginine vasopressin and endothelin. These humoral mediators act by:

- Increasing the heart rate and blood pressure
- Increasing the contractility of the ventricles, and
- Augmenting the ventricular preload—all in an attempt to sustain normal cardiac output to meet the needs of the body (**Flow chart 2**).

Once these compensatory mechanisms fail, clinical features of HF evolve. Thereafter, a series of *maladaptive cardiac responses* due to prolonged pulmonary congestion and anasarca ensue leading to a process of *myocardial remodeling* with myocardial hypertrophy or

Flow chart 1 Effect of untreated heart failure—low cardiac output state

Abbreviations: DIC, disseminated intravascular coagulation; MODS, multiple organ dysfunction syndrome; MOFS, multiple organ failure syndrome.

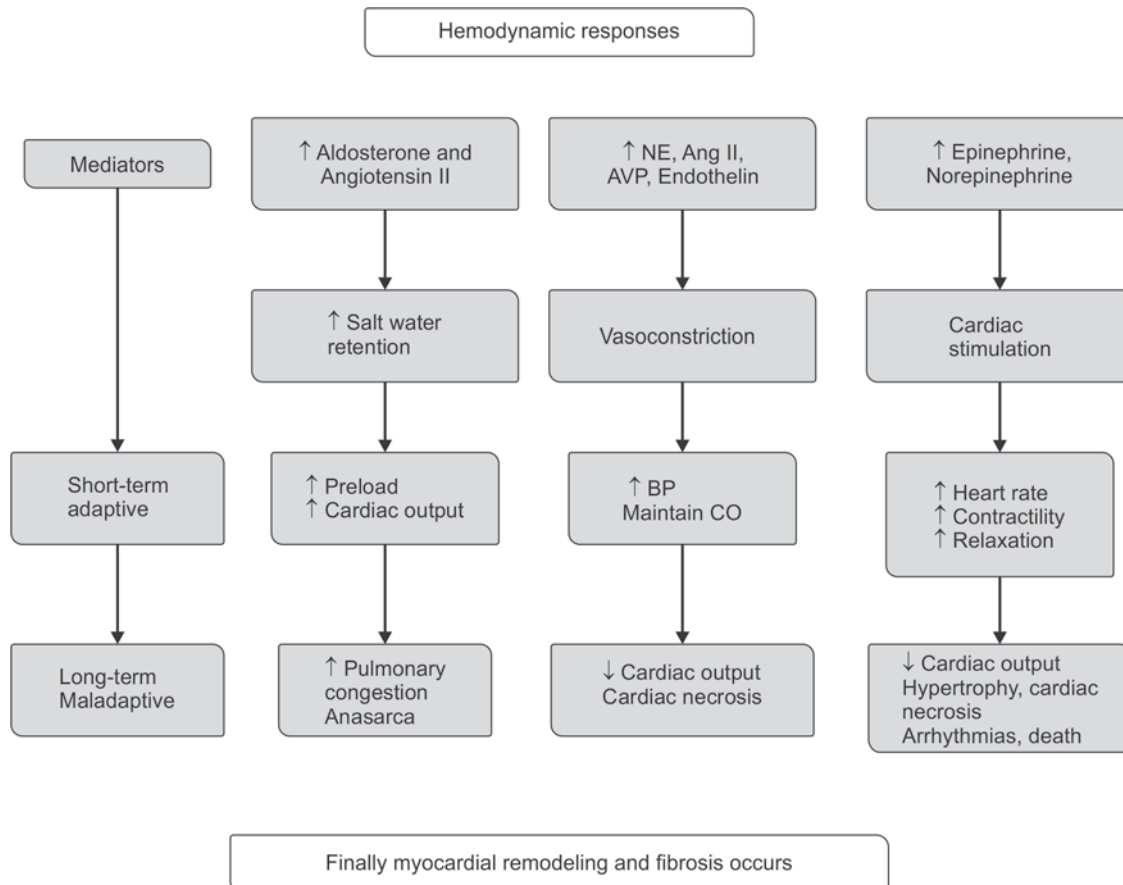

dilatation, fibrosis and gradually increasing myocardial apoptosis (programmed myocardial cell death). This myocardial remodeling leads ultimately to myocardial dysfunction and worsening or refractory heart failure with a tendency to malignant arrhythmias and finally death (**Flow chart 2**). These myocardial changes occur as

a result of—(1) upregulation of the renin-angiotensin-aldosterone system (RAS) causing greatly increased aldosterone levels and (2) sustained increasing levels of catecholamine (epinephrine, norepinephrine) and endothelin 1. A counter regulatory system evolves in the body with the release of cardiac hormones—atrial natriuretic peptide (ANP) and B type natriuretic peptide (BNP) in an attempt to neutralize the maladaptive neurohumoral responses. These hormones have the benefic effects of vasodilation and natriuresis. Thus, florid refractory HF can be interpreted as a major neurohumoral imbalance in the body with failure of the counter-regulatory system.

CLINICAL FEATURES (TABLE 4)

Once compensatory mechanisms fail, clinical features of HF develop. Left to right shunting or a protected pulmonary circulation in cyanotic heart disease, e.g., truncus arteriosus, double outlet RV cause pulmonary overcirculation and pulmonary congestion. Symptoms of HF in infants include resting tachypnea due to pulmonary congestion and secondary feeding difficulty leading to a suck-rest-suck cycle. There is often associated sweating or diaphoresis most prominent on the forehead. The feeding difficulty leads to failure to gain weight and finally weight loss. If florid HF develops then the infant may actually gain weight due to all the maladaptive responses (particularly upregulation of the RAS)—the increased aldosterone levels causing fluid retention and apparent weight gain.

Older children and young adults present typically with palpitations due to the compensatory tachycardia, and with worsening exercise tolerance progressing finally to breathlessness at rest and in the supine position.

Flow chart 2 Adaptive and maladaptive hemodynamic responses in heart failure

Abbreviations: Ang II, angiotensin II; NE, norepinephrine; AVP, arginine vasopressin; BP, blood pressure; CO, cardiac output.

Table 4 Symptoms and signs of heart failure (HF)

- Symptoms
 - Infants
 - Resting tachypnea
 - Feeding difficulty
 - Suck-rest-suck cycle
 - Diaphoresis
 - Failure to thrive
 - Older children
 - Palpitations
 - Exercise intolerance
- Signs
 - Chest retractions
 - Chest signs
 - Tachycardia
 - S₃ gallop
 - Puffiness around eyes
 - Hepatomegaly
 - Features of systemic congestion
 - Occasionally anasarca

Physical examination in infants reveals puffiness of the eyes, chest retractions exaggerated during feeding, along with chest signs—crepitations or crackles and hepatomegaly. In florid HF there may be anasarca along with desaturation in room air. Typically, pedal edema is not prominent in young infants. Cardiac evaluation classically shows tachycardia associated with an S₃ gallop. Chronic HF may also cause stunting with weight and height below the third centiles for age.

Patients with right heart dysfunction, such as pulmonary regurgitation in postoperative TOF or tricuspid regurgitation (rheumatic or Ebstein anomaly) predominantly have systemic venous congestion with prominent neck veins in older children and an increase in liver size.

INVESTIGATIONS

Exercise stress testing is only of relevance in older children and has little relevance in infants and small children. Biomarkers—B-natriuretic peptide and N-terminal pro-B-type natriuretic peptide are elevated in decompensated HF and have been used to titrate therapy in pediatric HF.

Chest X-ray

It reveals cardiomegaly and varying degrees of fluid in the lung parenchyma. There may be fissural fluid, small basal pleural effusions and occasionally florid pulmonary edema. Conditions with large left to right shunts or pulmonary overcirculation have increased pulmonary vascular markings or plethora. Sometimes the contour of the heart may provide a clue to the underlying structural heart defect, e.g., a hugely enlarged right atrium suggestive of tricuspid incompetence (**Figs 1 and 2**).

Electrocardiography

A normal electrocardiography (ECG) does not exclude HF. The most consistent finding is sinus tachycardia as a reflex response to HF. Other common findings are ST-T wave changes. ECG can validate findings of conduction delays and provide important clues to the causation of HF, e.g., left ventricular hypertrophy in LV pressure load conditions. It is important to note that ECG is not a sensitive indicator of ventricular volume loading.

Echocardiography

It is the single most important investigative tool in pediatric HF. A thorough study very effectively confirms or excludes structural

Figure 1 Hemorrhagic pulmonary edema in acute mitral regurgitation

Figure 2 Enlarged right atrium in heart failure (HF) due to tricuspid regurgitation

heart disease after which HF management can be appropriately planned. Echocardiography (Echo) also provides useful information about ventricular volumes and ventricular systolic and diastolic function. Thus, serial echoes can be used to monitor ventricular dysfunction and fine-tune therapy of HF.

Newer Noninvasive Imaging Tools

Computed tomography (CT) angiography and cardiac magnetic resonance imaging (MRI) are only used to clearly define and elucidate various structural anomalies and confirm and clarify anomalies suspected on an echocardiogram. Today, cardiac MRI is also an invaluable tool to serially accurately monitor ventricle volumes for more precise timing of valve replacement in pulmonary regurgitant lesions. Thus, today many new exciting imaging modalities are available which help finetune decision making in pediatric HF.

TREATMENT

The goals of treatment are: (1) to minimize the mismatch between metabolic demand and supply (2) improve cardiac output (3) relieve symptoms of HF and (4) correct or palliate underlying structural defect. Thus, optimal management of HF involves much more than rational drug therapy.

Minimize the Mismatch between Metabolic Demand and Supply

All attempts must be made to minimize the mismatch between metabolic supply and demand. Factors that increase metabolic demands such as fever, anemia, intercurrent infections, chest infections, endocarditis, hyperthyroidism, rheumatic activity, tachyarrhythmias must be assiduously looked for and aggressively treated. Oxygen therapy and good airway management are useful in reducing the work of breathing and improving tissue oxygen delivery. Increasingly, noninvasive ventilation with nasal continued positive airway pressure (CPAP) or bilevel positive airway pressure (BIPAP) is being used both to reduce the work of breathing as well as to improve cardiac output in situations of increased ventricular filling pressures. Assisted ventilation may be needed to optimize cardiac output and tissue oxygen delivery in *acute decompensated HF* or pulmonary edema. Therapeutic hypothermia or targeted temperature maintenance at 35–36°C has been shown to be useful in reducing metabolic demands in acute severe decompensated HF or cardiogenic shock. Planned *nutritional therapy* (NT) with hypercaloric gavage feeds in infants with HF has been shown to both reduce metabolic demands as well as to improve weight gain and growth. Hypothyroidism must be looked for and treated as it compounds HF.

Improving Cardiac Output: Drug Therapy

Heart failure therapy in children includes management of chronic HF as well as management of acute decompensation. This is achieved by a number of drugs that improve cardiac output and relieve symptoms. These drugs involve standard therapy—preload reducing agents (diuretics), drugs that enhance myocardial contractility (digoxin), afterload reducing agents (angiotensin-converting-enzyme inhibitors [ACEi]) and some drugs more recently evaluated. Drug therapy recommendations in pediatric HF has largely evolved from adult data and from collated clinical experience in children. Pediatric data even for standard drug therapy is limited and comprises of small studies, or case series with very few randomized controlled trials (RCTs). The 17th Expert Committee on the Selection and Use of Essential Medicines List for Children (EMLc) reviewed digoxin, diuretics, aldosterone inhibitors, ACE inhibitors, beta-blockers, inotropes angiotensin receptor blockers (ARBs) and some newer drugs for HF.

Digitalis

It is a glycoside with the following characteristics—positive inotropic effect with improvement in baroreceptor function, increased vagal tone, decrease in circulating norepinephrine levels, and possibly aldosterone antagonistic effects (reducing renin

levels)—thus improving oxygen demand supply balance. However, only one adult study—DIG trial showed some treatment benefit in NYHA class II–III adults with reduced hospitalizations but no mortality benefit with digoxin. There was no treatment benefit with digoxin in the PROVED and RADIANCE trials—in adults NYHA class II. There are no RCTs available in children.

Thus, there is no robust evidence to support the use of digoxin—the traditional mainstay of therapy for HF. However, due to long established clinical practice the expert committee recommended that digoxin be retained in the list of drugs for HF therapy. Dosages, etc., are mentioned in **Table 5**. Drug interactions with carvedilol need to be remembered. So, currently, digoxin usage in HF is dependent on unit practices and preferences.

Diuretics

These have been considered to be a fundamental part of HF management particularly in volume loaded ventricles. The rationale for use has been the increased sodium and water loss induced by diuretics. Again no large RCTs are available in pediatric literature. Diuretics from different groups (a–c) can be combined for greater efficacy: (a) Loop diuretics, e.g., furosemide, torasemide, (b) Thiazides: Hydrochlorothiazide, metolazone (thiazide-related drug), and (c) Aldosterone antagonists, e.g., spironolactone and eplerenone.

Furosemide It continues to be the principle drug used in volume-overload conditions to decrease pulmonary congestion and thus decrease the work of breathing. The rationale for the use of furosemide is the increased water and salt loss through the kidney. Long-term use has been associated with sensorineural hearing loss in a small number of patients. However, currently it is the least toxic diuretic and one for which maximum experience is available. Torasemide is a loop diuretic more potent than furosemide, (10 mg of torasemide is equivalent to 40 mg of furosemide), has a higher bioavailability and a longer duration of action. In an open label study on children, torasemide was considered superior to furosemide for control of HF. However, it is currently not recommended for routine use.

A phenomenon associated with diuretic use is *braking* or refractory edema induced by increasing resistance to diuretic use with reducing urine output. Adult data has shown that combination therapy with thiazides or with metolazone increased sodium and water excretion with improved diuretic efficacy. A small pediatric study has also confirmed treatment benefit with combination of furosemide and metolazone.

No large RCTs on diuretics are available in children. The evidence for furosemide use is based on the adult Cochrane data base 2006: 14 studies with 514 participants (adults) showed

Table 5 Usual digitalizing and maintenance dosages for digoxin in children with normal renal function based on lean body weight

Age	IV digitalizing dose (µg/kg)	Daily IV maintenance dose (µg/kg)
Premature	15–25	20–30% of the IV digitalizing dose
Full term	20–30	25–35% of the IV digitalizing dose
1–24 months	30–50	
2–5 years	25–35	
5–10 years	15–30	
Over 10 years	8–12	

- Rapid digitalization is usually not indicated in heart failure (HF). Digoxin *holiday* is generally not needed in children. The half-life of digoxin is markedly prolonged in preterm babies and in renal dysfunction. Dose of digoxin should be halved when using amiodarone. IV digitalizing doses are 80% of oral digitalizing doses. Divided daily dosing is recommended for children under 10 years of age. Digitalizing dose: ½ dose stat and remaining dose in 6–8 hours interval depending upon clinical response.
- Digoxin has a narrow therapeutic range. Side effects include arrhythmias—sinus bradycardia, sinoatrial and atrioventricular blocks, atrial ectopics, atrial tachycardia with block, ventricular arrhythmias including ventricular tachycardia (VT); *gastrointestinal*—nausea, vomiting, abdominal pain and diarrhea; *central nervous system*—lethargy, confusion, disorientation, seizures; and ocular—blurred vision, diplopia, photophobia.

improvement in exercise capacity and reduced risk of both deterioration and death. A review of pediatric HF in 2004 concluded that furosemide should be part of the treatment pathway for HF in children. So, due to widespread availability and longstanding use, furosemide has been retained as the diuretic of choice in the list of essential drugs recommended by the expert committee (EMLc). While combination therapy with intermittent dosing of metolazone may be useful in *resistant edema* neither metolazone or other thiazides are currently included in the EMLc list due to lack of robust evidence.

Aldosterone antagonists (Spironolactone) The rationale for use are its multiple effects apart from reduced sodium and water retention. These drugs have the additional benefic effect of: (1) an improvement in tachycardia—improving oxygen demand-supply balance, (2) reduced myocardial apoptosis and fibrosis, and (3) antiarrhythmic effect. A landmark adult paper—randomized aldactone evaluation study (RALES) showed significant reduction in both mortality and symptoms. In pediatrics, there is very little robust evidence for treatment benefit but preliminary data indicates that spironolactone may reduce myocardial hypertrophy and fibrosis in chronic HF. If so, the incidence of malignant arrhythmias and sudden death may also diminish. So, though the evidence for spironolactone use in pediatrics is modest it is still included in the EMLc.

Thus, current recommendations are that in pediatric HF loop diuretics—furosemide be used as first-line drugs and many units worldwide would combine it with spironolactone for its potential multiple benefic effects.

Angiotensin-converting Enzyme Inhibitors (Captopril, Enalapril, Ramipril)

These drugs improve cardiac output by *afterload reduction*. ACE inhibitors antagonize the actions of angiotensin II. They decrease the effect that occurs from activation of the RAS system that occurs in HF. The beneficial effects of ACE inhibitors are: reduced angiotensin II mediated vasoconstriction, potentiation of sympathetic nervous system activity and reduced angiotensin II mediated aldosterone release. Thus, benefic effects include reduced sodium and water retention, reduced myocardial fibrosis and reduced inhibition of nitric oxide release along with reduced breakdown of vasodilatory bradykinin. Thus, the net effects are the reduction in systemic afterload along with symptomatic improvement.

Today, ACEi therapy is the mainstay of outpatient therapy for adults with HF. The evidence in children includes only one RCT which showed no benefit, the rest being case series. Majority of the case series showed some clinical benefit, some even showed survival benefit with some demonstrating improvement in LV function and hypertrophy. The adverse effects noted were hypotension, renal injury and occasionally death in very bad hemodynamic substrates. So, it is uncertain if the death could be directly attributed to the drugs. Another important side effect is a troublesome cough which is caused due to decreased breakdown of vasodilatory bradykinin. The cough resolves on cessation of the drugs.

A recent review in 2006 concluded that ACEi must be used in children with ventricular dysfunction and that use in valvar insufficiency is also appropriate and effective. Left to right shunts should be surgically treated and not managed with ACEi inhibitors. ACEi may be given only if surgery is not appropriate. The maximum pediatric data is on captopril and enalapril though enalapril has the advantage of less dosing requirements—once to twice/day. Captopril is given at least three times daily.

ACEi are not included in the EMLc but has been strongly recommended for inclusion in the list. Captopril has been proposed as most representative. Our practice is to use ACEi for ventricular dysfunction and occasionally for residual valve regurgitant lesions.

Angiotensin Receptor Blockers (Losartan, Candesartan)

The rational for use is that they reduce angiotensin II mediated vasoconstriction, potentiation of sympathetic activity and angiotensin II mediated aldosterone release. There is today increasing evidence that they offer therapeutic benefit in adults with HF. However, there is little data in children to support their use in HF and it is currently not recommended for use in pediatric HF and is not included in the EMLc.

Hydralazine

It is a peripheral vasodilator that is safe in patients with renal impairment as it does not produce much hyperkalemia. The starting dose is 0.75 mg/kg/day which may be increased gradually up to maximum of 5 mg/kg/day in four divided doses in patients who do not tolerate ACEi.

Beta-blockers (Carvedilol, Metoprolol)

Beta-blockers act by the following mechanisms—they cause slowing of heart rate—improving oxygen demand supply balance, reduce myocardial apoptosis and myocardial fibrosis. They also have anti-arrhythmic effect, vasodilatory and antioxidant properties and most important show synergism with ACE inhibitors. β -blockers were viewed previously with skepticism but currently they are the standard of care in adults with HF. Carvedilol, a third generation β -ARB is the most commonly used drug. Pediatric literature includes only retrospective small studies involving carvedilol, metoprolol. Some RCTs have also been done. One RCT showed no clear cut benefit. Majority of the studies show improvement in symptoms, systolic function, and synergism with other therapy. Higher doses are needed as compared to adults. β -blockers are not included in the EMLc list but there are strong recommendations to include carvedilol in addition to other conventional therapy. Current practice in many units including ours is to use carvedilol as adjunctive therapy for systolic ventricular dysfunction (cardiomyopathy, myocarditis and congenital heart disease).

Table 6 provides dosages of the drugs (other than digitalis) used to treat heart failure in children.

Management of Acute Decompensation

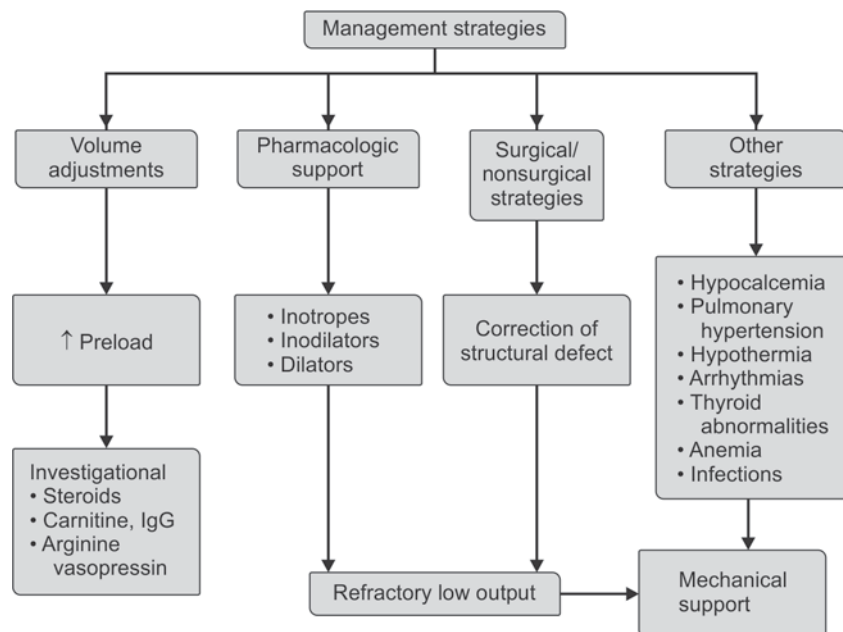

Many children present to the pediatric emergency room (ER) with acute decompensation in HR and its management remains a challenge. The investigative tools essentially remain the same as highlighted in the text earlier, that is to assess the degree and cause of decompensation and to investigate for any precipitating cause—*anemia, infections, endocarditis, etc.* A generalized management approach is highlighted in the **Flow chart 3**.

Gentle volume augmentation and judicious use of inotropic agents remains the initial approach for any child presenting with acute decompensation. Before the use of inotropic agents occult hypovolemia needs to be recognized and treated. The preload needs to be monitored by measuring the central venous pressure (CVP). Edema should be avoided and preload optimization needs to be done judiciously. The volume augmentation needs to be within the narrow range of the curve from B to C wherein there is no edema or pleural collection (**Fig. 3**).

Fluid overload in acute HF and pulmonary edema are best treated with intravenous furosemide—infusions combined with bolus dosing being most effective. In the absence of a satisfactory response to intravenous furosemide, furosemide infusion (0.2–1 mg/kg/hour) is often effective in initiating a brisk diuretic response and improving pulmonary congestion.

Table 6 Drugs for treating heart failure in children

Drug	Dosage	Side effects
<i>Furosemide (Lasix)</i>	<i>Neonate:</i> 0.5–1 mg/kg IV/IM q8–24 hour; maximum dose 2 mg/kg <i>Children:</i> 1–2 mg/kg PO/IV/IM; increase by 1–2 mg/kg, maximum dose: 6 mg/kg <i>Infusion dose:</i> 0.1 mg/kg/hour, can be doubled every 2 hours to maximum 1 mg/kg/hour	Hypokalemia, hyponatremia Metabolic acidosis, hyperuricemia Hyperglycemia Ototoxicity Nephrocalcinosis
<i>Spironolactone (Aldactone)</i>	<i>Neonate:</i> 1–3 mg/kg/day PO every 12–24 hours <i>Children:</i> 1.5–3.3 mg/kg/day PO in divided doses every 6–12 hours	Hyperkalemia (in renal failure) Gynecomastia Irregular menses, amenorrhea Gastritis, GI bleeding
<i>Metolazone</i>	0.1–0.2 mg/kg/day PO in single daily dose or divided q12 hourly	Severe hypokalemia Dry mouth, excessive thirst Weakness, drowsiness Light headed, restlessness Numbness, tingling sensation Palpitation, chest pain Decrease urine output
<i>Enalapril</i>	PO: 0.08 mg, maximum 0.5 mg/kg/day q12 hourly; not to exceed 5 mg/day	Hypotension (initial doses) Cough
<i>Captopril</i>	<i>Neonates:</i> 0.05–0.1 mg/kg dose q8–24 hour; maximum 0.5 mg/kg/dose <i>Infants:</i> 0.15–0.5 mg/kg/dose q8–24 hour; maximum 6 mg/kg/day <i>Children:</i> 0.3–1.0 mg/kg/dose q8–24 hour; maximum 6 mg/kg/day. Maximum 2 mg/kg/dose	First dose hypotension, cough Loss of taste sensation Insomnia Skin itching and rashes Drowsiness, headache
<i>Carvedilol</i>	Initial dose 0.05 mg/kg/dose twice daily. Increase every 2 weeks by 0.05 mg/kg/dose for the first increment then by 0.1 mg/kg/dose for the next increment, aiming for a maintenance dose of 0.35 mg/kg/dose given twice daily (not more than 25 mg twice daily)	Bronchoconstriction Bradycardia Heart block Hypotension Weight gain Giddiness

Flow chart 3 Management of acute decompensated heart failure**Inotropes, Inodilators****(Dopamine, Dobutamine, Milrinone)**

These drugs are used since they increase myocardial performance and cardiac output. Milrinone is an effective inodilator since it also decreases afterload. Indications for use include acute heart failure, cardiogenic shock and acute exacerbation of chronic heart failure (infections, anemia). Inotropy and lusitropy are synergistic

in improving cardiac output and dobutamine or dopamine may be judiciously combined with milrinone. Cardiogenic shock and acute deterioration are rarely sudden and typically result from gradual unrecognized deterioration. A meticulous and thorough echo examination is imperative to exclude structural, intrinsic and restrictive heart disease. It is also important to avoid a situation of increasing catecholamine dosing which would finally lead to catecholamine resistance (**Flow chart 4**). Alternative treatment

Figure 3 Preload and stroke volume/cardiac output

modalities other than high dose catecholamines need to be explored.

Hypocalcemia and Calcium Supplementation

Calcium is an essential part of the contraction and relaxation cycle of the myocardium and is often overlooked when HF is being treated. The neonatal and infant myocardium is particularly sensitive to extracellular calcium. It is the most common cause of systolic ventricular dysfunction in infancy in India. It is certainly the most easily correctable cause of ventricular dysfunction. Hypocalcemia is commonly seen in neonates, small infants especially if growth reduced or, malnourished or on diuretic therapy.

Indications for calcium supplementation are If ionic Ca less than 0.9 mmol/L, calcium infusion is required in the form of Ca gluconate 10%, 0.4 mL/kg/hour—titrated to ionic calcium levels—target levels being 1.2 mmol/L. Our protocol is to collect blood samples for vitamin D, parathyroid and alkaline phosphatase levels before initiating therapy for hypocalcemia.

Miscellaneous Modalities

Intravenous Immunoglobulins

Intravenous immunoglobulin (IVIg) is an immunomodulator, affecting B- and T-lymphocyte function and is known to neutralize

pathogenic antibodies and suppress their synthesis. IVIg is considered useful in the acute stage of viral replication and is part of the care pathway for acute viral myocarditis in infants who present with acute HF. Infants with elevated cardiac enzymes (Class IIa) or those with evidence of the acute nature of the illness on MRI are candidates for therapy.

Anticoagulant Drugs

Heart failure with severe ventricular dysfunction predisposes to clot formation, secondary strokes and pulmonary embolism. Those with gross HF and severe ventricular dysfunction should receive oral anticoagulants (Class I). Oral anticoagulants are also preferred for children with cardiomyopathy who have significant ventricular dysfunction (left ventricular ejection fraction [LVEF] < 20%) (Class IIa). The target international normalized ratio (INR) is kept between 2.0 and 3.0. If intracavitary thrombus or marked dilatation of atria with spontaneous contrast is present, anticoagulant therapy is again warranted (Class I).

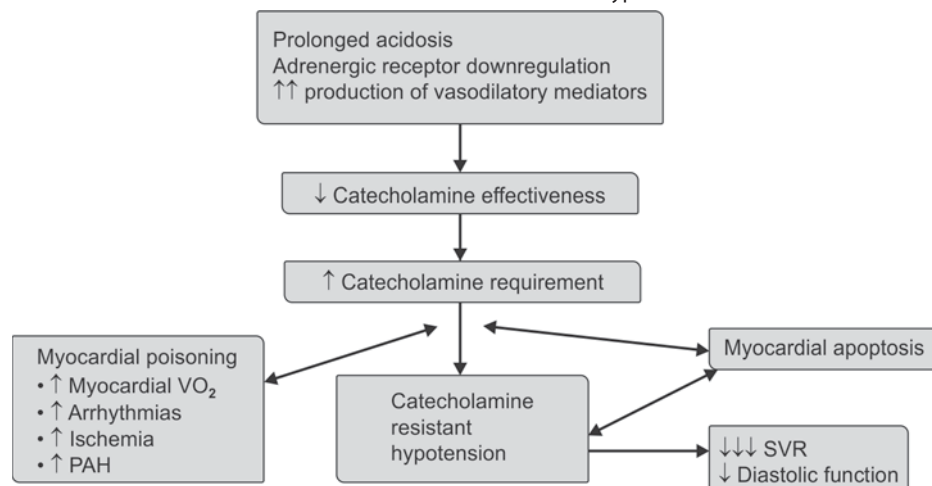

Catheter or Surgical Interventions

Structural heart disease with pressure overload conditions, e.g., aortic stenosis, coarctation of aorta, can cause severe acute left ventricular systolic dysfunction and acute HF with or without pulmonary edema. In severe cases, prostaglandin E1 infusion may be necessary to keep the ductus arteriosus open so that the systemic blood supply is maintained from the pulmonary artery via the PDA-aorta. Treatment of HF in this circumstance requires optimizing hemodynamics followed by urgent intervention—catheter intervention or balloon valvuloplasty for aortic valvar stenosis and emergency surgery for coarctation of aorta. Similarly, severe pulmonary valvar stenosis is managed by balloon valvuloplasty. Likewise, anomalous origin of left coronary artery from pulmonary artery may present with acute HF and severe left ventricular dysfunction on echo mimicking myocarditis to the unwary. Early surgical correction after initial stabilization is essential. Ventricular systolic function usually improves rapidly after catheter or surgical interventions with resolution of HF.

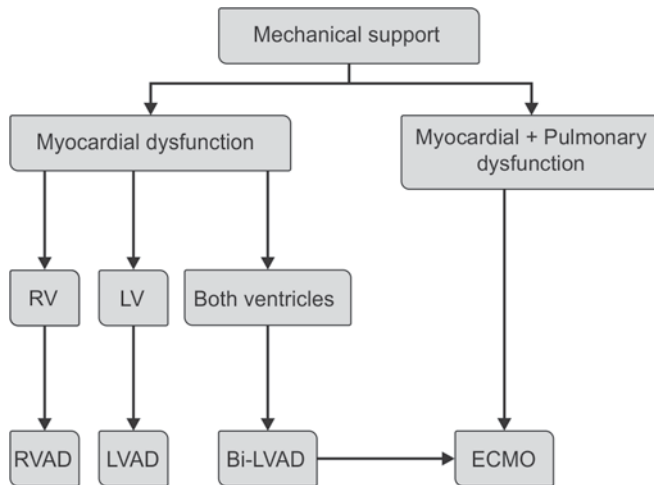

Mechanical Circulatory Support

The challenge in acute pediatric heart failure is that frequently infants and children present with severe left ventricular or biventricular dysfunction not readily responsive to drug therapy. These are typically children with severe myocarditis or end-stage cardiomyopathy. Mechanical circulatory support (MCS) management (**Flow chart 5**) is *acute* or *long-term*.

Flow chart 4 Catecholamine resistant hypotension

Abbreviations: PAH, pulmonary arterial hypertension; SVR, systemic vascular resistance.

Flow chart 5 Mechanical circulatory support (MCS)

Abbreviations: VAD, ventricular assist device; ECMO, extracorporeal membrane oxygenation.

Acute mechanical support or extracorporeal life support (ECLS) is of two types: (1) ventricular assist device (VAD) is a type of mechanical support that supports the ventricles and is less invasive; (2) extracorporeal membrane oxygenation (ECMO) is highly invasive and supports both the heart and the lungs. Both need prolonged anticoagulation, are highly labor intensive and highly expensive with an approximate discharge mortality of 50% (ELS organization registry). ECLS is also associated with significant side effects, e.g., bleeding, strokes, infection.

It must be remembered that ECLS is a bridge to recovery or to heart transplantation. The number of patients on the heart transplant recipient list is ever increasing worldwide and a decision to offer ECLS as *rescue therapy* should be carefully considered by the entire team. ECLS is not to be offered as destination therapy or as indefinite chronic therapy since it is not geared to provide long-term support.

Long-term mechanical support includes paracorporeal devices and implantable devices. Long-term MCS may be used as rescue therapy, temporary therapy, i.e., a bridge to transplantation or destination therapy, i.e., partial or complete myocardial recovery. These include—(1) pneumatic pulsatile pediatric ventricular assist devices (VADs)—The Berlin Heart EXCOR: These extracorporeal systems have provided successful MCS in children of all ages. They provide a long-term bridge to heart transplantation while allowing extubation, ambulation, and active physical therapy, unlike ECMO or centrifugal pump VADs. (2) The Micromed DeBakey VAD Child: This system has also been successfully used as a bridge to transplantation in cases which are NYHA Class IV end stage HF and are refractory to medical therapy.

Outpatient Treatment for Chronic Refractory Heart Failure

Inotropes, Inodilators (Dopamine, Dobutamine, Milrinone)

Inotropes have been traditionally used in acute HF for stabilization in severe acute cases, e.g., myocarditis. Also, they act as a bridge to cardiac intervention or surgery. In Chronic HF, they have been given in adults weekly on an outpatient or day admission basis. Short pulses of low-dose inotropes have been shown to reduce hospital admissions as well as provide symptomatic relief. They act as a bridge to recovery or transplantation. Some units have tried this strategy in children with chronic HF with varying success.

Newer Drugs in Severe Heart Failure

Nesiritide (synthetic brain natriuretic peptide) has been shown to increase diuresis in HF and improve renal failure with reduction in systemic venous congestion and considerable relief in symptoms.

Levosimendan is a calcium sensitizer and a potent inodilator agent. It offers *cardioprotection*—a new paradigm in the management of HF. It has also been used for *postoperative rescue* in severe infant low cardiac output state as well as in cardiogenic shock due to acute myocarditis after failure of conventional inotropy.

Surgical and Device Therapy

Pacemaker and Implantable Defibrillator

The indications for pacemaker in infants having HF are ventricular bradycardia or tachyarrhythmias. Implantable defibrillator is used in congenital heart disease patients who have syncope or tachycardia.

Cardiac resynchronization therapy (CRT) Dyssynchrony in myocardial contraction commonly occurs in patients with HF and left bundle branch block, leading to impaired LV function and worsening mitral regurgitation. CRT restores normal contraction to the LV wall while improving overall heart function. This should be considered after optimizing conventional drug therapy. Clear cut indications for CRT in adults are laid down. In pediatric patients CRT has been successfully tried in postoperative TOF patients with dyssynchrony. Its long-term benefit, though is yet to be established.

Continued Positive Airway Pressure

CPAP is an effective treatment for chronic HF. It has been shown to improve left ventricular dysfunction and cardiac output along with relief of symptoms. Domiciliary CPAP may be used in children with chronic HF due to cardiomyopathy or ventricular dysfunction due to myocarditis.

Other Surgical Strategies

Other surgical alternates for chronic decompensated HF include Batista operation or partial left ventriculectomy, myosplint device/Acorn cardiac device and passive restraint devices. All of these are intended to reshape the ventricle but are not associated with consistent success in controlling HF. *Heart transplant* has recently been performed in children.

Nutrition and Exercise in Heart Failure

Nutritional therapy with appropriate calories and proteins is of paramount importance in infants with congenital heart disease and has been discussed earlier in this chapter. Sodium restriction is not a requirement in children. Furthermore, limiting sodium can cause delayed body and cerebral growth. Normal physical activity should be continued in children with HF. Limiting exercise has not shown any favorable results. Published data has shown that cardiac rehabilitation programs led to sustained improvements in exercise function in children with HF. However, children with HF should not be permitted to participate in competitive sports.

Future Directions

Several new drugs are in various stages of clinical application. These include adenosine antagonists, nitric oxide modulators, natriuretic peptides, xanthine oxidase inhibitors.

Stem Cell Therapy

A promising modality represents the first realistic strategy for reversing the effects of what has until now been considered *terminal heart damage*. Many cell types have been successfully transplanted into damaged myocardium, including fetal cardiomyocytes, skeletal myoblasts, embryonic stem cells and bone marrow-

derived stem cells. The skeletal myoblast, an immature muscle cell that retains the ability to proliferate seems to be the most promising. It remains to be seen if engraftment of these cells leads to long-term improvements in LV function.

Gene Therapy

Gene transfer The three different biological pathways that play a crucial role in the pathophysiology of HF and form the target for gene therapy include intracellular calcium signaling, β_1 -adrenergic receptor (β_1 -AR) signaling, and antiapoptotic signaling. Intracoronary delivery of a recombinant adenovirus has been shown to improve global left ventricular function. Large clinical trials with long-term follow-up are needed before recommendations can be made.

IN A NUTSHELL

1. The prevalence of pediatric heart failure (HF) is less as compared to adults but the overall impact of pediatric HF is still considerable and is expected to increase with time.
2. Clinical assessment of severity of HF is important to titrate therapy.
3. Structural heart disease must be carefully looked for in pediatric HF. Once excluded it is important to assiduously search for various easily treatable metabolic and other causes of reversible HF.
4. Pathophysiology of myocardial failure is important to guide management. *Myocardial pump failure* occurs due to ventricular systolic, diastolic dysfunction or abnormal ventriculoarterial coupling, i.e., an exaggerated, inappropriate or abnormal afterload on a normal myocardium. The cause of myocyte dysfunction is today thought to be multifactorial in etiology. This multifactorial etiology has implications for therapy.
5. Heart failure (HF) can be interpreted as a major neurohumoral imbalance in the body with failure of the body's compensatory mechanisms.
6. Diagnosis of HF in pediatrics is largely clinical. The cause can be usually confirmed on echocardiography. Echocardiography also provides information on systolic and diastolic ventricular function as well as ventricle volumes. Thus serial echoes are useful in monitoring HF therapy. Serial biomarkers have also been shown to be useful in titrating and fine-tuning HF management. Cardiac MRI is more accurate than echo for ventricular volumes.
7. Provisional recommendations for drug therapy in HF constitute conventional modalities—digoxin, furosemide, spironolactone and inotropes in acute decompensated HF. There are strong recommendations to include ACE inhibitors (captopril/enalapril) and beta-blockers (carvedilol) as adjunctive therapy for HF management.

Chapter 40.34

Infective Endocarditis

Shakuntala Prabhu, Sumitra Venkatesh

Infective endocarditis (IE) is defined as an *endovascular microbial infection of cardiovascular structures*. It is a serious infection associated with significant morbidity and mortality and is becoming more frequently recognized in children and adolescents. Since the first description by William Osler in 1885, many advances have been made in its diagnosis and therapy. But due to the occult nature of this disease, the primary physician must have a high degree of suspicion to make an early diagnosis so as to institute prompt and appropriate antibiotic treatment for optimal outcome and prevent disease related complications.

EPIDEMIOLOGY

Incidence

Most children with IE have an identifiable risk factor for the disease. The incidence and epidemiology of IE has changed in recent times. The cumulative risk of IE up to 18 years of age was reported to be 6.1 per 1,000 children. Factors implicated for the increase in incidence of bacterial endocarditis are given in **Table 1**.

The median age of IE has however reduced from 8 years to 1.5 years. 42% of children with IE have an underlying congenital heart disease (CHD). In developing country like India, rheumatic heart disease continues to be an important cause of IE. Hospital-acquired IE is on the rise and causative pathogens are nonstreptococcal and nonstaphylococcal microbes.

Risk Factors

There are definitive risk factors identified for the occurrence of IE in children and adults (**Table 2**). A prior history of endocarditis is an important independent risk factor for subsequent IE; reported recurrence risk ranges from 2.5% to 9%. Patients with CHD in which blood is ejected at high velocity through a defect or a stenotic orifice are the most susceptible. The other CHDs predisposing to IE include left ventricular regurgitant lesions, coarctation of the aorta and tetralogy of Fallot. Vegetations usually form at the site of the endocardial or intimal erosion resulting from the turbulent flow.

Surgical correction of CHD may reduce, but does not eliminate the risk of endocarditis, with the exception of repair of a simple atrial septal defect or patent ductus arteriosus. Children who have undergone valve replacement or valved conduit repair are at particularly high-risk. As a corollary, cardiac lesions like secundum atrial septum, mitral valve prolapse with low velocity flows are at low-risk for IE.

Table 1 Factors implicated for the increase in incidence of bacterial endocarditis

1. Increase in postcardiac surgery survival for congenital heart diseases (CHDs)
2. Application of innovative cardiac surgical techniques
3. Use of prosthetic tubes and valves for surgery
4. Use of indwelling vascular catheters in infants admitted to intensive care units
5. Lack of awareness amongst the physicians, dentists, and general public, about the threat of IE and the preventive measures available

Table 2 Risk factors for bacterial endocarditis

Congenital heart diseases (CHD)	Bicuspid aortic valve Ventricular septal defect Patent ductus arteriosus Semilunar valvular stenosis Coarctation of the aorta Tetralogy of Fallot Left ventricular regurgitant lesions Cardiomyopathies
Acquired heart diseases	Rheumatic valvular heart diseases: Mitral regurgitation (MR), mitral stenosis (MS), combined MS and MR Aortic regurgitation and aortic stenosis Cardiomyopathies
	Postsurgical: Valve replacement with prosthesis, Conduit repair for CHDs Insertion of intracardiac devices (i.e., defibrillators or pacemakers)
Risk for right-sided IE	Indwelling catheters in intensive care units*

*Right-sided IE of the heart are associated with a very high mortality rate especially in neonates

Abbreviation: IE, infective endocarditis

In approximately 30% of patients with IE, a predisposing factor is recognized. A surgical or dental procedure can be implicated in approximately 65% of cases in which the potential source of bacteremia is identified. Poor dental hygiene in children with cyanotic heart disease results in a greater risk for endocarditis. Endocarditis from oral flora may occur without a preceding dental procedure. In these children, the occurrence of endocarditis directly after heart surgery is relatively low, but it is frequently an antecedent event.

PATHOGENESIS

The endothelial surface, initially injured by shearing forces caused by turbulent blood flow becomes susceptible to formation/deposition of noninfected thrombus comprising of fibrin, platelets and occasional red blood cells. Secondary bacteremia/fungemia in these children results in adherence of microbial pathogens to the injured endocardium and thrombus. Finally, fibrin and platelet deposition over the infected vegetation results in formation of a protective sheath that isolates the organisms from host defenses and permits rapid proliferation of the infectious agent. Subsequent involvement of other organs due to embolization or immune-mediated processes causes the complications of the disease.

MICROBIOLOGY

Infective endocarditis is also commonly referred to as bacterial endocarditis because bacteria are the predominant microbial pathogens; however, nonbacterial endocarditis can be caused by viruses, fungi, and other microbiological agents/microorganisms. It is believed that gram-positive cocci have a predilection for subendocardial connective tissue, especially fibronectin that gets exposed when endocardium is damaged. Viridans-type streptococci (α -hemolytic streptococci 20%) and *Staphylococcus aureus* (57%) are the leading causative agents responsible for endocarditis in children. *Escherichia coli* (2%), *Streptococcus pneumoniae* (1%), and *Haemophilus influenzae* (1%) are other bacterial microorganisms. Certain organisms are characteristically associated with some specific predisposing factors (**Table 3**).

Table 3 Characteristic organisms with specific predisposing factors

Commonly seen organism	Predisposing factors
<i>Staphylococcus aureus</i> IE	Native valves*
Viridans group streptococcal IE	Dental procedures
Group D enterococci IE	Lower bowel or genitourinary manipulation
Coagulase-negative staphylococci IE	Indwelling central venous catheter and use of high glucose concentrations parenteral nutrition especially in premature infants
<i>Pseudomonas aeruginosa</i> or <i>Serratia marcescens</i> IE	Intravenous drug users
Fungal IE [#]	Open heart surgery

* Presents as an acute fulminant process with a high mortality;

[#] Fungal IE vegetations are frequently large, rapidly increasing and friable with a tendency to embolize.

Abbreviation: IE, infective endocarditis.

Culture Negative Endocarditis

It is seen in 5–7% of children, although this incidence is higher in a series reported from India. The causes include previous administration of antimicrobial agents; inadequate microbiological techniques; infection with highly fastidious bacteria or nonbacterial pathogens; and filtering of bacteria originating from right-sided cardiac chambers, by the lungs.

CLINICAL FEATURES

Infective endocarditis in children has variable manifestations depending on the underlying cardiac disease and involvement of other organs secondary to embolization, the immunologic responses and virulence of the causative agent.

Subacute Presentation

Prolonged low-grade fever, fatigue, arthralgia, myalgia, weight loss, exercise intolerance, pallor, headache, diaphoresis and often microscopic hematuria, a feature of immunologically mediated glomerulonephritis are the usual presentations. A search for the peripheral stigmata of endocarditis, including evidence of small and large emboli with special attention to the fundi, conjunctivae, skin, and digits should be undertaken. Petechiae are present on the skin of the extremities or on mucous membranes such as the palate. Hemorrhages on the conjunctivae are usually seen on eversion of the eyelids. Splinter hemorrhages are nonblanching, linear, reddish-brown lesions found under the nail bed. Roth spots, Janeway lesions and Osler's nodes (features of vasculitis produced by circulating antigen-antibody complexes) are more specific findings of IE, though rare in children, must be looked for. Roth spots are exudative, edematous hemorrhagic lesions of the retina. Janeway lesions are macular, nonpainful, erythematous lesions on the palms and soles and Osler's nodes are painful, violaceous nodules found in the pulp of fingers and toes. Septic embolizations are not uncommon and result in small or major arterial occlusions with infective infarctions in extracardiac organs (e.g., osteomyelitis or pneumonia). The less virulent pathogens, such as *viridans* group streptococci and coagulase-negative staphylococci, are usually the causative agents for subacute IE.

Acute Infective Endocarditis

Acute IE has a progressive, fulminant course with features of high spiking fevers, rapidly changing symptoms and signs and deteriorating cardiac functions with cardiogenic shock

necessitating urgent, aggressive and appropriate therapy. It has rapid destruction of heart valve tissue, abscess formation and embolic phenomena responsible for the hyperacute clinical presentation and hence is associated with significant morbidity and high mortality. *S. aureus* is the usual causative agent.

Right-sided cardiac lesions are noted in patients with native endocarditis or catheter-related IE. They may have few or no specific cardiovascular signs but may present with primarily pulmonary symptoms and signs secondary to septic pulmonary embolization.

The symptoms and signs of IE in children are listed in **Table 4**. Splenomegaly, septic emboli to skin (petechiae or purpuric rashes), microscopic hematuria and a high C-reactive protein (CRP) value of more than 100 mg/L are important clues to the diagnosis of IE as reported by Liew et al.

Neonatal Infective Endocarditis

In neonates, the signs and symptoms of IE are nonspecific. They include feeding intolerance, tachycardia, respiratory distress, hypotension, and a new or changing murmur. Fever may be absent and persistently positive blood cultures may be the only clue to diagnosis. Fungal IE is more common in the neonates and may present as acute fulminant course with septicemia or heart failure.

DIAGNOSIS

The diagnosis of IE is based on the history, physical examination, blood culture, laboratory results, and an echocardiogram. The modified Duke criteria is the most commonly used among several available diagnostic criteria for IE.

Duke Criteria

The modified Duke criterion is divided into major and minor findings. The clinical diagnosis of definitive IE requires the presence of either two major criteria, one major and three minor criteria, or five minor criteria (**Tables 5 and 6**).

- **Major clinical criteria** (1) Positive blood cultures (two separate cultures for a usual pathogen, two or more for less typical pathogens); and (2) Echocardiographic: Evidence of endocarditis (intracardiac mass on a valve or other sites, regurgitant flow near a prosthesis, abscess, partial dehiscence of prosthetic valves, or new valve regurgitant flow).
- **Minor clinical criteria** Predisposing conditions, fever, embolic-vascular signs, immune complex phenomena (glomerulonephritis, arthritis, rheumatoid factor, Osler nodes, and Roth spots), a single positive blood culture or serologic

Table 6 Complications of infective endocarditis

• Congestive heart failure
• Pericarditis
• Cardiac valvular insufficiency
• Embolic events, e.g., cerebral, pulmonary, renal, coronary (Stroke syndromes)
• Persistent bacteremia or fungemia
• Periannular extension of abscess, Sinus of Valsalva aneurysm and intracardiac fistula
• Prosthetic device dysfunction including valvular dehiscence
• Arrhythmia or development of new heart block
• Aortic root or myocardial abscesses
• Mycotic aneurysms
• Glomerulonephritis/acute renal failure
• <i>Metastatic abscess:</i> Mesenteric or splenic abscess or infarct

evidence of infection, and echocardiographic signs not meeting the major criteria.

Despite the above criteria, IE remains a clinical diagnosis and a high index of suspicion is warranted in any child at risk for IE (those with pre-existing heart disease or indwelling central venous catheter) in the presence of fever without a focus.

Laboratory Tests

Culture Collection

Blood cultures provide the critical information for institution of appropriate treatment of IE. All others are secondary in

importance. As bacteremia in IE is usually continuous, it is not necessary to obtain the cultures during fever only. Routinely, three blood cultures (2–3 mL of blood) under strict aseptic precautions are recommended in children. In 90% of cases of endocarditis, the causative agent is recovered from the initial two blood cultures. If there is no growth by 2nd day, two more blood cultures may be drawn in case antibiotics have not been started. Unless otherwise suspected, blood cultures are usually performed for aerobic organisms. Delayed cultures especially on enriched media are necessary to detect fastidious bacteria or fungi.

Each set of cultures should be obtained from separate venipuncture sites, and ideally blood cultures should not be obtained from a vascular catheter. If the patient is not acutely ill, antibiotic therapy can be withheld for 24–48 hours while the blood cultures are obtained. The diagnostic yield is better in the absence of recent antimicrobial therapy.

Interpreting Culture Results

The Duke criteria for the diagnosis of endocarditis define certain organisms as *typical causes* of IE (**Table 5**). The risk of endocarditis in patients with *S. aureus* bacteremia is particularly high. False-positive cultures are due to contamination during blood collection and present a special problem, as bacteria found on the skin may also themselves cause IE. *Propionibacterium acnes*, *Corynebacterium* spp., *Bacillus* species, and coagulase-negative staphylococci are the usual pathogens. The probability of pathogenicity is increased if the organism is observed in multiple blood cultures obtained by independent venipunctures.

Culture-negative Endocarditis

It should be considered in patients with negative blood cultures and persistent fever with one or more clinical findings consistent with infective endocarditis (IE) (e.g., stroke or other manifestations of emboli) and/or those with echo-demonstrated vegetations. In children with persistent fever and suspected IE, serologic diagnosis is necessary to detect unusual or fastidious microorganisms like *Coxiella burnetii*, *Bartonella* spp., *Chlamydophila* spp., *Legionella* spp., and *Brucella*.

Echocardiography

Echocardiography has a key role in the diagnosis of IE. An echocardiogram should be performed on all patients in whom there is a reasonable suspicion of IE, as it may detect the presence of a vegetation; a major diagnostic Duke criterion (**Table 5**). It helps to demonstrate the vegetation (**Figs 1 and 2**), presence and severity of valvar destruction, assesses the degree of valvar regurgitation, predict embolic complications (lesions greater than 1 cm and fungating masses are at greatest risk for embolization) and presence of complications like paravalvar leak, myocardial abscess, etc., are echo findings considered to represent *Major Duke Criteria*. Other abnormal echocardiographic findings not fulfilling the definitions are considered as minor criteria.

The diagnostic yield of echocardiography is influenced by the image quality, size of vegetation, (vegetation < 2–3 mm may not be well seen), location of vegetation (e.g., vegetation on a

prosthetic valve are difficult to visualize) and experience of the echocardiographer. Transthoracic echocardiography (TTE) is more sensitive in children than in adults due to better acoustic windows. Indications for transesophageal echocardiography (TEE) in children are in select conditions and include:

- Inadequate TTE imaging as in overweight or muscular children
- Those with high clinical suspicion of IE and a negative TTE
- Children with significant respiratory disease that limits TTE
- Children with complex congenital heart disease (CHD)
- Status postrepair as artifacts from prosthetic material (grafts and conduits) and valves which may interfere with TTE imaging
- Aortic valve endocarditis or aortic root abscess on TTE
- Paravalvar damage and valve dehiscence due to prosthetic valve infection
- Right-sided vegetations.

The limitations of echocardiography are: (1) False negative results with small vegetations or in embolized vegetations; (2) not all echogenic masses are necessarily vegetations; and (3) inability to differentiate active vegetation from an old sterile vegetation. Once treatment is completed, a repeat evaluation may be necessary to establish a new baseline of valvar and myocardial functions for the patient.

Other Tests

Hemoglobin is low. Erythrocyte sedimentation rate (ESR) and CRP are elevated. Urinalysis shows hematuria, proteinuria, and red cell casts suggestive of glomerulonephritis. ECG may reveal a first degree or complete heart block which suggests vegetations with periannular extension. Magnetic resonance imaging (MRI) of the brain may be useful in children with definite or suspected IE with neurological symptoms.

DIFFERENTIAL DIAGNOSIS

The differential diagnosis includes an alternate source of infection in a bacteremic patient with underlying heart disease, skin and soft tissue infection, cardiac device infection, intravascular catheter infection, musculoskeletal infection, meningitis and pneumonia. Other illnesses in children with overlapping symptoms and signs as seen in IE, include blood malignancies, collagen-vascular disease, Kawasaki disease, myocarditis, rheumatic fever and vasculitis.

MANAGEMENT

The principles of management of IE in children are antimicrobial therapy, timely surgical intervention in selected cases and monitoring for complications.

Figure 1 Two-dimensional (2D) echocardiogram showing aortic valve endocarditis

Figure 2 Two-dimensional (2D) echocardiogram showing vegetations on tricuspid valve (native endocarditis)

Antimicrobial Therapy

Antibiotics being the mainstay of treatment for IE, their choice, dosage, and duration of treatment are dependent upon the underlying causative microbial agent's identity and susceptibility. There are minor differences, in recommended treatment guidelines for specific microorganism, amongst the American Heart Association (AHA), British Society for Antimicrobial Chemotherapy (BSAC), and the European Society for Cardiology (ESC). Bactericidal antibiotics should be started empirically after blood cultures are collected, if the patient is acutely ill. However, if the child is stable, it would be advisable to wait for 48 hours till antibiotic sensitivity testing is carefully reviewed. If cultures are negative two additional cultures should be done.

Empiric Antibiotic Treatment

It is generally directed to the most common pathogens, i.e., streptococci, staphylococci and enterococci. The chosen antibiotics must be given intravenously to attain persistently high bactericidal concentrations. Duration of therapy in patients with native valve endocarditis ranges from 2 weeks to 6 weeks, depending on the pathogen and site of valvar infection. Infection of prosthetic valves and tissue, infection with highly virulent or more resistant pathogens may require longer treatment usually 6–8 weeks. Prolonged therapy is often necessary to eradicate organisms that are growing in relatively inaccessible avascular vegetation. Guidelines recommended by AHA are summarized as follows:

1. *Penicillin-susceptible streptococcal endocarditis (PSSE) on native cardiac valve* Penicillin G for 4 weeks or penicillin or ceftriaxone combined with gentamicin for 2 weeks.
2. *Penicillin-resistant streptococcal endocarditis (PRSE) on native cardiac valves* Penicillin, or ampicillin, or ceftriaxone for 4 weeks, combined with gentamicin for the first 2 weeks.
3. *PSSE on a prosthetic valve or other prosthetic material* Penicillin G or ampicillin, or ceftriaxone for 6 weeks, combined with gentamicin for the first 2 weeks.
4. *PRSE on a prosthetic valve or other prosthetic material* Penicillin G or ampicillin, or ceftriaxone for 6 weeks, combined with gentamicin for the first 2 weeks; vancomycin can be used in patients who cannot tolerate penicillin or ceftriaxone. The duration of penicillin-resistant therapy for streptococcal endocarditis on a prosthetic valve is 6 weeks.
5. *Susceptible enterococcal infection on native valves* Penicillin or ampicillin, combined with gentamicin, for 4–6 weeks.
6. *Susceptible enterococcal infection on prosthetic material* should be treated for at least 6 weeks.
7. *Methicillin-susceptible S. aureus (MSSA) infection on native valves* Nafcillin or oxacillin for at least 6 weeks with 3–5 days of optional gentamicin.
8. *Methicillin-resistant S. aureus (MRSA) infection on native valves* Vancomycin for at least 6 weeks, with or without 3–5 days of gentamicin.
9. *MSSA infection on prosthetic tissue* Nafcillin or oxacillin plus rifampin for at least 6 weeks, in combination with gentamicin for 2 weeks.
10. *MRSA infection on prosthetic tissue* Vancomycin plus rifampin for at least 6 weeks, in combination with gentamicin for 2 weeks.
11. *Gram-negative endocarditis caused by HACEK organisms* Ceftriaxone or ampicillin plus gentamicin for 4 weeks.

Linezolid or daptomycin are options for patients with intolerance to vancomycin or resistant organisms. Substitution of linezolid for vancomycin should also be considered in patients

with unstable renal function because of the difficulty of achieving therapeutic trough levels. Repeat blood cultures and ESR may be necessary to assess complete response though clinical response is often sufficient. Use of recombinant tissue plasminogen activator to lyse intracardiac vegetations in severely ill infants has been mentioned in literature. Digitalis, salt restriction, diuretic therapy and other standard protocol should be instituted in supportive care of heart failure.

Fungal Endocarditis

Intravenous amphotericin B is the first-line antifungal therapy for IE in children. Renal parameters must be monitored closely, as it is highly nephrotoxic. Duration of therapy is prolonged and generally for 6–8 weeks, followed by oral antifungal agents like fluconazole. The total duration of treatment for eradication may be 1 year or more. 5-fluorocytosine may have an additive effect when combined with amphotericin B. However, the superiority of two drug combination over amphotericin B alone has not been proven by randomized trial. Medical therapy alone is often not successful and surgical intervention is often necessary.

Surgical Intervention

Surgical intervention should be contemplated early if the likely result is more favorable than with medical management, based upon an echo-guided analysis of the relative risks and benefits. About one-fifth of patients require surgery in acute phase. The goals of surgery are to eradicate the focus of infection, to repair cardiac defects and to prevent development of complications. Indications for surgery during the acute phase of IE are:

- Continued bacteremia or persistent fever after 2 weeks of appropriate antibiotic therapy
- Worsening heart failure due to valvar regurgitation
- Embolic events; systemic, pulmonary, coronary, or cerebral
- Myocardial or periannular abscess
- Pathogens those are difficult to cure with medical therapy alone like *Pseudomonas aeruginosa*, *Brucella*, and fungal endocarditis
- *Leaflet perforation*, or sinus of Valsalva aneurysm
- Mobile vegetations more than 10 mm in the setting of severe valve regurgitation or stenosis
- Prosthetic valve dysfunction like valve dehiscence.

Postoperatively, a full course of antimicrobial therapy starting from the time of surgery is warranted and at times antibiotics changed according to culture sensitivity of organisms grown on operative valve/tissue cultures. Late surgery may be indicated in some patients after the IE has been controlled, e.g., in a patient with small ventricular septal defect with a previous episode of IE.

COMPLICATIONS

Despite the use of antibiotic agents, mortality remains at 20–25%. Serious morbidity occurs in 50–60% of children with documented IE. Complications can occur before, during, and after completion of therapy. Cardiac complications include cardiac failure, perivalvar abscess, pericarditis, and intracardiac fistula. Congestive heart failure can occur secondary to ruptured leaflets or chordae and is the most common cause of death. Development of a new onset heart block may suggest perivalvar extension of infection. Large (> 10 mm), mobile vegetations are more likely to embolize. Embolization can occur even up to 2–4 weeks after starting antibiotic therapy. Metastatic infection due to septic emboli may result in septic arthritis, vertebral osteomyelitis, and pneumonia,

distal abscesses in the kidneys, spleen, brain or soft tissues. Septic emboli can occlude or damage any vessel in the systemic or pulmonary arterial circulation. More than one complication can occur simultaneously (**Table 6**).

Risk factors for IE complications include prosthetic cardiac valves; left-sided valvar involvement; *S. aureus* or fungal IE; previous IE; prolonged symptoms more than or equal to 3 months; complex cyanotic CHD; systemic-to-pulmonary shunts, conduits, or other prostheses; poor clinical response to antimicrobial therapy; and prematurity.

PROPHYLAXIS

Though antibiotic prophylaxis was being practiced for many decades to prevent IE, evidence to support antimicrobial prophylaxis as an effective preventive measure is weak and inconclusive. Also the risk of antibiotic-associated adverse events exceeds the benefit. For these reasons, AHA in 2007 simplified its recommendations—guidelines for the prevention of IE in children. Today, antibiotic prophylaxis is given only to those who are at the highest risk for IE (**Table 7**).

These guidelines emphasize that IE is much more likely to result from frequent exposure to random bacteremia associated with daily activities than from bacteremia caused by a dental, gastrointestinal (GI) tract or genitourinary (GU) tract procedures. Thus, now there is a great emphasis on maintaining good orodental hygiene as poor dental hygiene is responsible for a large proportion of IE cases. Following highest risk procedures may result in transient bacteremia:

- All dental procedures that involve manipulation of either gingival tissue or the periapical region of teeth or perforation of the oral mucosa would warrant antibiotic prophylaxis. Routine anesthetic injections through noninfected tissue, taking dental radiographs, placement or adjustments of removable prosthodontic or orthodontic appliances, and bleeding from trauma to the lips or oral mucosa *do not* require IE prophylaxis
- Procedures of the respiratory tract that involve incision or biopsy of the respiratory mucosa
- Procedures in patients with ongoing GI or GU tract infection
- Procedures on infected skin, skin structure, or musculoskeletal tissue
- Surgery to place prosthetic heart valves or prosthetic intravascular or intracardiac materials.

Table 8 Regimen of antibiotic prophylaxis prior to dental procedures

Situation	Agent	Regimen: Single dose 30–60 min before procedure Dose/kg (maximum dose/adult dose)
Oral	Amoxicillin	50 mg/kg (2 g)
Unable to take oral medication	Ampicillin or Cephazolin or Ceftriaxone	50 mg/kg IM or IV (2 g) 50 mg/kg IM or IV (1 g)
Allergic to penicillin or ampicillin (Oral)	Cephalexin or Clindamycin or Azithromycin or Clarithromycin	50 mg/kg (2 g) 20 mg/kg (600 mg) 15 mg/kg (500 mg)
Allergic to penicillins or ampicillin and unable to take oral medication	Cephazolin or Ceftriaxone or Clindamycin phosphate	50 mg/kg IM or IV (1 g) 20 mg/kg IM or IV

The choice of antibiotic is patient and procedure specific (**Table 8**) and have to be administration only once, 30–60 minutes prior to the procedure. The applicability of these guidelines in India is not very clear. Hence, good orodental health should be addressed to the patient/parent during each follow-up visit.

IN A NUTSHELL

1. Infective endocarditis (IE) is a serious infection, associated with significant morbidity and mortality and is increasingly being recognized in children and adolescents.
2. Most children with IE have an identifiable risk factor for the disease. IE should be part of the differential diagnosis of a persistent febrile or inflammatory illness, particularly if there are pre-existing cardiac lesions.
3. The diagnosis of IE is based on clinical findings, positive blood cultures, laboratory results, and an echocardiogram. The modified Duke criterion is the most commonly used among several available diagnostic criteria for IE.
4. The principles of management of IE in children are prolonged antimicrobial therapy, timely surgical intervention in selected cases and monitoring for complications.
5. Despite the use of antibiotic agents, serious morbidity occurs in 50–60% and mortality in 20–25%. Complications can occur before, during, and after completion of therapy.

Chapter 40.35

Myocardial Diseases:
Myocarditis and
Cardiomyopathies

Ronak Naik, Nishant Shah

MYOCARDITIS

Myocarditis refers to myocardial inflammation caused by various infectious and noninfectious agents and is pathologically characterized by inflammatory cell infiltrates and myocyte necrosis or degeneration. Myocarditis can be acute or chronic.

ETIOLOGY

In the past, many cases of myocarditis remained undiagnosed because of its insidious onset of the disease process, benign course and lack of sophisticated virological identification techniques. Viral infections got identified as the most common cause of proven myocarditis in older children and adults by endomyocardial biopsy (EMB). It remained difficult to prove the viral etiology in acute myocarditis and acute onset dilated cardiomyopathy (DCM) cases in infants and young children because of infrequent use of this invasive procedure. With the development of new molecular techniques such as polymerase chain reaction (PCR) and in situ hybridization, it is possible to identify the viral genome responsible for myocarditis.

Recent literatures suggest that parvovirus B19 and human herpesvirus 6 are more commonly identified in patients with myocarditis, compared to enterovirus and adenovirus in the 1990s and early 2000s. Common infectious and noninfectious causes of myocarditis are listed in **Table 1**.

PATHOPHYSIOLOGY

In the acute or early phase, viral infection of myocytes occurs, resulting in viral replication; cytolysis of infected myocyte soon follows from direct injury. In the subacute phase, activation of cell-mediated immunity, while trying to clear the viral infection, further aggravates the myocardial damage from cell-mediated cytotoxicity. In a subset of patients, chronic perpetuation of myocardial inflammation leads to ongoing myocardial damage. Viral persistence and autoimmunity with or without genetic predisposition have been widely speculated to be responsible for the sequelae.

Flow chart 1 shows the pathophysiologic sequences in myocarditis and its progression to DCM.

Mumps and coxsackievirus B3 have been identified in the myocardium of infants with endocardial fibroelastosis. Coronary insufficiency is common with parvovirus B19 myocarditis in children. Arrhythmias including complete heart block are frequent complications of diphtheritic myocarditis. Giant cell myocarditis (GCM) is a rare but severe form of myocarditis characterized by the presence of multinucleated giant cells and extensive myocardial necrosis. It is thought to be autoimmune in origin.

CLINICAL FEATURES

Myocarditis has wide spectrum of presentation, from subclinical disease to life-threatening events such as cardiogenic shock and significant arrhythmias. In children, presentation depends

Table 1 Causes of myocarditis

Infections	
RNA viruses	Coxsackievirus A and B, echovirus, mumps virus, measles virus, rubella virus, hepatitis C virus, respiratory syncytial virus, influenza A and B virus, human immunodeficiency virus-1
DNA viruses	Parvovirus B19, human herpes virus-6, cytomegalovirus, adenovirus, Epstein-Barr virus, varicella virus, herpes simplex virus
Bacterial	Mycoplasma, Staphylococcus and Streptococcus spp. Corynebacterium diphtheriae, Salmonella typhi, mycobacteria
Rickettsial	Coxiella burnetti, Rickettsia typhi
Spirochetal	Borrelia burgdorferi, Leptospira
Fungal	Candida, Aspergillus, Cryptococcus
Parasitic	Echinococcus granulosus, Trichinella spiralis
Protozoal	Toxoplasma gondii, Trypanosoma cruzi
Noninfectious causes	
Autoimmune	Kawasaki disease, rheumatic fever, systemic lupus erythematosus, rheumatoid arthritis, celiac disease, Churg-Strauss syndrome, Crohns disease, ulcerative colitis, dermatomyositis, giant cell myocarditis, hypereosinophilic syndrome
Toxic	Drugs: Anthracyclines, cyclophosphamide, 5-fluorouracil, catecholamines, cocaine, amphetamines Metals: Copper, iron, arsenic, lead Physical agents: Radiation Hormones: Pheochromocytoma Other: Ethanol
Hypersensitivity	Penicillin, ampicillin, cephalosporins, tetracyclines, sulfonamides, antiphlogistics, benzodiazepines, clozapine, loop and thiazide diuretics, methyl dopa, tetanus toxoid, tricyclic antidepressants

Abbreviations: RNA, ribonucleic acid; DNA, deoxyribonucleic acid.

on the age. Newborns and infants can have feeding difficulties, vomiting, irritability, pallor and respiratory distress. Older children and adolescents can present with poor appetite, low-grade fever, general malaise, chest pain, palpitation and exercise intolerance.

Physical examination is consistent with signs of congestive heart failure such as tachypnea, tachycardia, poor peripheral circulation, hepatomegaly, gallop (S₃) and holosystolic murmur from mitral regurgitation.

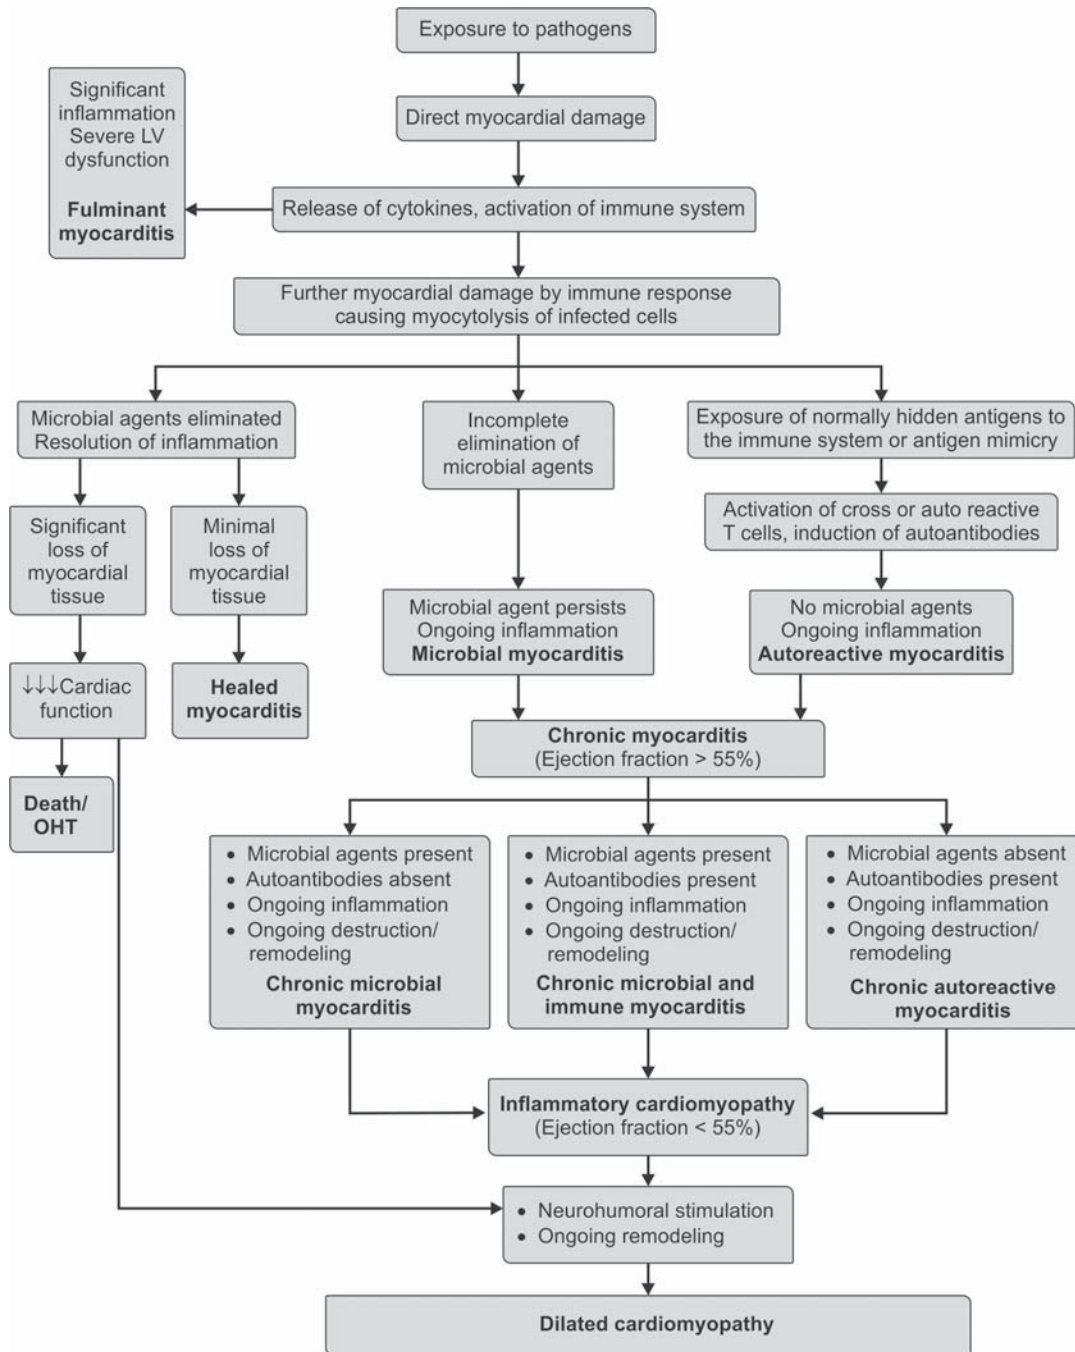

DIAGNOSIS

Electrocardiography

Findings include sinus tachycardia, low voltage QRS complex, ST elevation, T wave inversion and nonspecific T wave changes; however these findings are not sensitive and specific for myocarditis. Various arrhythmias such as ventricular tachycardia, atrial fibrillation, supraventricular tachycardia and atrioventricular (AV) block may occur.

Echocardiography

Assessment of myocarditis with evaluation of chamber size and wall thickness, ventricular function (systolic as well as diastolic), regional wall motion abnormalities, valvar (i.e., mitral) regurgitation and pericardial effusion are all possible with echocardiography.

Flow chart 1 Pathophysiology of myocarditis and dilated cardiomyopathy

Abbreviation: OHT, orthotopic heart transplantation.

Cardiovascular Magnetic Resonance Imaging

Cardiovascular magnetic resonance imaging (CMR) has greatly enhanced our ability to characterize myocardial inflammation. In addition to volume and functional data, information on myocardial edema (T2 weighted images), hyperemia (T1 weighted contrast enhanced images) and area of necrosis and fibrosis from late gadolinium enhancement is very useful to diagnose active inflammation.

Endomyocardial Biopsy

It is considered as the gold standard to diagnose myocardial inflammation. EMB however being invasive carries a small but measurable risk of myocardial perforation or the development of

untoward hemodynamic or arrhythmic events in children during the catheterization and biopsy. Involvement of myocardium often is patchy and scattered which reduces the sensitivity of EMB to diagnose myocarditis. For all these reasons, many centers do not perform EMB routinely in children with suspected myocarditis. When used, EMB should be performed by an experienced team, and tissue obtained from EMB should be analyzed using histology, immunochemistry and viral PCR.

Based on the Dallas criteria, myocarditis can be classified as active, borderline or no myocarditis, depending on the presence of an inflammatory infiltrate with (active) or without (borderline) myocyte degeneration or necrosis.

Others

Erythrocyte sedimentation rate (ESR), C-reactive protein (CRP) and brain natriuretic peptide levels are often raised in myocarditis. 35–45% of EMB-proven myocarditis cases have elevated troponin.

Viral culture from various specimens such as blood, stool or urine is commonly performed but is unreliable in identifying the causative infection.

Viral serology often leads to incorrect diagnosis because of the high prevalence of IgG antibodies in the general population and positive serology does not confirm myocardial infection.

MANAGEMENT

Treatment of myocarditis depends on the severity of illness and presenting symptoms. Standard heart failure therapy should be initiated according to the New York Heart Association (NYHA) functional class.

Diuretics help the children with breathing difficulties and congestion. *Angiotensin-converting-enzyme (ACE) inhibitors* and *angiotensin II receptor blockers (ARBs)*—afterload reducing agents should be considered in children with decreased left ventricular function. Use of *intravenous immunoglobulin (IVIG)* in children with acute myocarditis has shown improvement of left ventricular function in one study; however, there was no benefit from IVIG in adult patients with myocarditis compared to placebo. Nevertheless, IVIG has no major side effects and may be used in myocarditis in children. Treatment with *immunosuppressive agents* such as cyclosporine, prednisolone and azathioprine in acute myocarditis remains controversial. Infectious disease specialists should be consulted while considering the use of specific *antiviral therapies*, including use of interferon. Extracorporeal membrane oxygenation (ECMO) and/or a mechanical cardiopulmonary assist device may be needed as a bridge to recovery or to heart transplantation in patients with hemodynamic instability.

Follow-up

After resolution of the clinical presentation (at least 6 months after the onset of the disease), clinical reassessment is indicated before the child resumes competitive sport. All patients with myocarditis should be followed with clinical assessment, electrocardiography (ECG), and echocardiography.

PROGNOSIS

The outcome of myocarditis depends on age at the time of presentation, etiology and presence or absence of ventricular dysfunction. Neither the severity of inflammation nor the detection of viral genome has been shown to be a predictor of poor outcome. Nearly 50% of cases resolve without long-term complications. However, newborns and infants have a significantly higher mortality rate compared to older children and adolescents (75% vs. 10–25%) diagnosed with myocarditis.

CARDIOMYOPATHIES

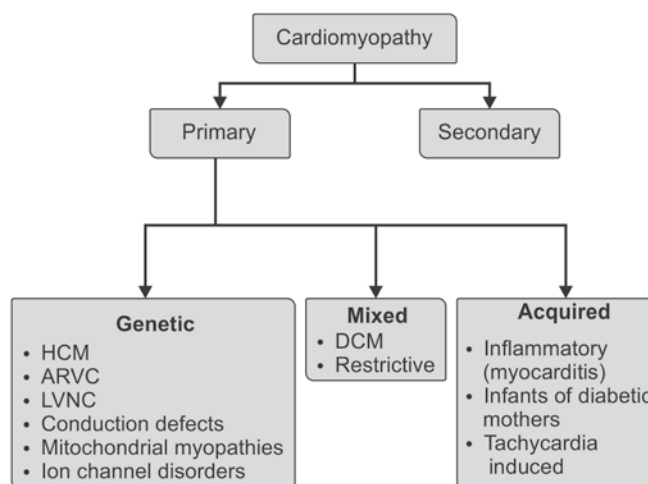

Cardiomyopathies refer to a heterogeneous group of diseases of the myocardium associated with mechanical and/or electrical dysfunction, usually exhibiting inappropriate ventricular hypertrophy or dilatation. Though they are of varied causes, mostly they are genetic.

CLASSIFICATION

Cardiomyopathies are classified into two major groups (**Flow chart 2**).

1. *Primary cardiomyopathies* Here, the disease state is solely or predominantly confined to myocardium. Hypertrophic

Flow chart 2 Classification of cardiomyopathies

Abbreviations: DCM, dilated cardiomyopathy; HCM, hypertrophic cardiomyopathy; ARVC, arrhythmogenic right ventricular cardiomyopathy; LVNC, left ventricular noncompaction.

cardiomyopathy (HCM) and DCM resulting from genetic mutations are examples of primary cardiomyopathies. Primary cardiomyopathies are further divided into genetic, mixed (genetic and nongenetic) and acquired.

2. *Secondary cardiomyopathies* Myocardial involvement is part of generalized systemic disorders involving other organ systems. HCM in Noonan syndrome and DCM in neuromuscular disorders such as Duchenne muscular dystrophy are the examples. The mixture of morphology and physiology inherent within this classification can lead to overlapping cases.

DILATED CARDIOMYOPATHY

Prevalence

Dilated cardiomyopathy is the most common form of cardiomyopathy in children with a prevalence of 36.5 per 100,000, needing early heart transplantation. In Asian populations the incidence is 1.9–3.6 per 100,000 person-years. Cardiac dilatation with decreased systolic function is the unique feature of DCM.

Etiology

Various primary and secondary causes of DCM (**Table 2**) leading to myocardial damage share similar phenotypic clinical presentations. In children, up to two-thirds cases of DCM are idiopathic. The most common known causes of DCM are myocarditis, neuromuscular disorders and familial DCM. About 20–50% of DCM patients have a familial form of the disease caused by more than 37 genetic mutations (**Figure 1**), the most common being mutations in TTN (titin), MYH7 (beta-myosin heavy chain) and MYH6 (alpha-myosin heavy chain) gene.

Pathophysiology

In DCM, all the four cardiac chambers are dilated with atrial dilation in proportion to ventricular dilation resulting characteristically in progressive impairment of systolic performance of the ventricles. Compensatory neurohumoral activation mechanisms are able to restore cardiovascular function to a normal homeostatic range for a short period of time. However, with time the sustained activation of these systems can lead to secondary end-organ damage within the ventricles, worsening left ventricle (LV) remodeling (chronic myocyte death, increased myocardial mass from interstitial fibrosis, and ventricular dilation and wall thinning due to slippage

Table 2 Etiology of primary and secondary dilated cardiomyopathy

Idiopathic	Two-thirds cases
Familial	Autosomal dominant (most common), X-linked, autosomal recessive, mitochondrial
Myocarditis	Acute or chronic (described in detail elsewhere)
Neuromuscular disease	Muscular dystrophies (Duchenne's, Becker, limb-girdle, Emery-Dreifuss), myotonic dystrophy, Friedreich's ataxia, tuberous sclerosis, neurofibromatosis
Infection	Viral, bacterial, fungal, parasitic, rickettsial, spirochetal (detailed in myocarditis section)
Nutritional	Beriberi (thiamine), pellagra, scurvy, selenium, carnitine, kwashiorkor
Drugs	Anthracyclines, sympathomimetics, antiretroviral agents, cyclophosphamide, radiation therapy
Endocrine	Thyroid disorders, hypoparathyroidism, pheochromocytoma, diabetes, acromegaly
Metabolic	Glycogen storage diseases, mucopolysaccharidoses, mitochondrial disorders, organic acidemias (propionic), fatty acid oxidation disorders, carnitine transport disorders, hemochromatosis, amyloidosis
Ischemic	Atherosclerosis, Kawasaki disease, anomalous origin of the left coronary artery from pulmonary artery (ALCAPA)
Chronic arrhythmias	Atrial and ventricular
Collagen vascular disease or autoimmune diseases	Systemic lupus erythematosus, rheumatoid arthritis, dermatomyositis, polyarteritis nodosa
Toxins	Cobalt, lead
Others	Systemic hypertension, peripartum

of aligned myocytes) and subsequent cardiac decompensation (**Figs 2A and B**). Current heart failure treatment is targeted to reverse or reduce this maladaptive remodeling.

Clinical Features

Dilated cardiomyopathy usually has insidious onset. Superimposed respiratory infection may result in acute decompensation. A history of preceding viral illness is not uncommon in acquired forms of DCM secondary to myocarditis. A detailed family history is important and is positive in 20–48% of cases of DCM. Presenting symptoms and physical findings are described in **Table 3**. The diagnostic investigative work-up and findings of DCM are described in **Table 4**.

Prognosis

Dilated cardiomyopathy is the most common cause of heart transplantation in adult and children. The reported 1 year and 5 year survival rates in idiopathic DCM are 63–90% and 20–80%. The prognostic predictors of survival are given in the **Table 5**.

Management

The treatment objectives of the DCM:

- To treat congestive heart failure
- To treat/prevent arrhythmia
- To treat/prevent thromboembolic complications
- To correct underlying etiology.

The anticongestive therapy addresses increased fluid retention, low cardiac output and increased peripheral vasoconstriction. Treatment is described in **Tables 6 and 7**.

HYPERTROPHIC CARDIOMYOPATHY

The past nomenclature for HCM includes idiopathic hypertrophic subaortic stenosis (IHSS) or hypertrophic obstructive cardiomyopathy (HOCM). HCM is now a widely accepted term and it includes both, obstructive and nonobstructive forms of HCM.

HCM is a disease state characterized by unexplained left ventricular hypertrophy (LVH) associated with nondilated

ventricular chambers in the absence of another cardiac or systemic disease being entirely responsible for the magnitude of hypertrophy evident in a given patient.

Clinically, HCM is usually recognized by maximal LV wall thickness more than or equal to 15 mm, with wall thickness of 13–14 mm considered borderline, particularly in the presence of other compelling information (e.g., family history of HCM). In children, increased LV wall thickness in HCM is defined as wall thickness more than or equal to 2 SD (SD = standard deviation) above the mean (Z score ≥ 2) for age, sex, or body size.

Epidemiology/Genetics

Hypertrophic cardiomyopathy, an autosomal dominantly inherited condition with a prevalence of 0.2% (1:500) in the general population is the most common cause of sudden cardiac death in young athletes. It presents in all age groups from infancy to the very elderly. There are about 1,500 identified mutations in almost 11 genes encoding the contractile component of sarcomeres. 70% of these mutations belong to the β -myosin heavy chain and myosin-binding protein C (MYBPC). Recent literature has suggested that a mutation in *MYBPC3* is associated with cardiomyopathy and heart failure in South Asian populations. This 25-bp deletion mutation has been found in 4% of individuals in the Indian subcontinent with higher prevalence reported from western and southern India. Lately an emerging subgroup has been identified known as *genotype-positive phenotype-negative* group.

Pathophysiology

The most characteristic abnormality is left ventricular hypertrophy (LVH) with a preserved or smaller left ventricular cavity. The most common form of HCM is asymmetrical septal hypertrophy followed by symmetric, apical and lateral wall hypertrophy. Histopathologically, HCM is characterized by myocardial disarray, myocardial scarring and abnormalities of small intramural coronary arteries. Left ventricular outflow tract (LVOT) obstruction, LV diastolic dysfunction, mitral valve abnormalities, myocardial ischemia and arrhythmias are important pathophysiological abnormalities responsible for various clinical presentations. LVOT obstruction is of a dynamic variety and occurs primarily

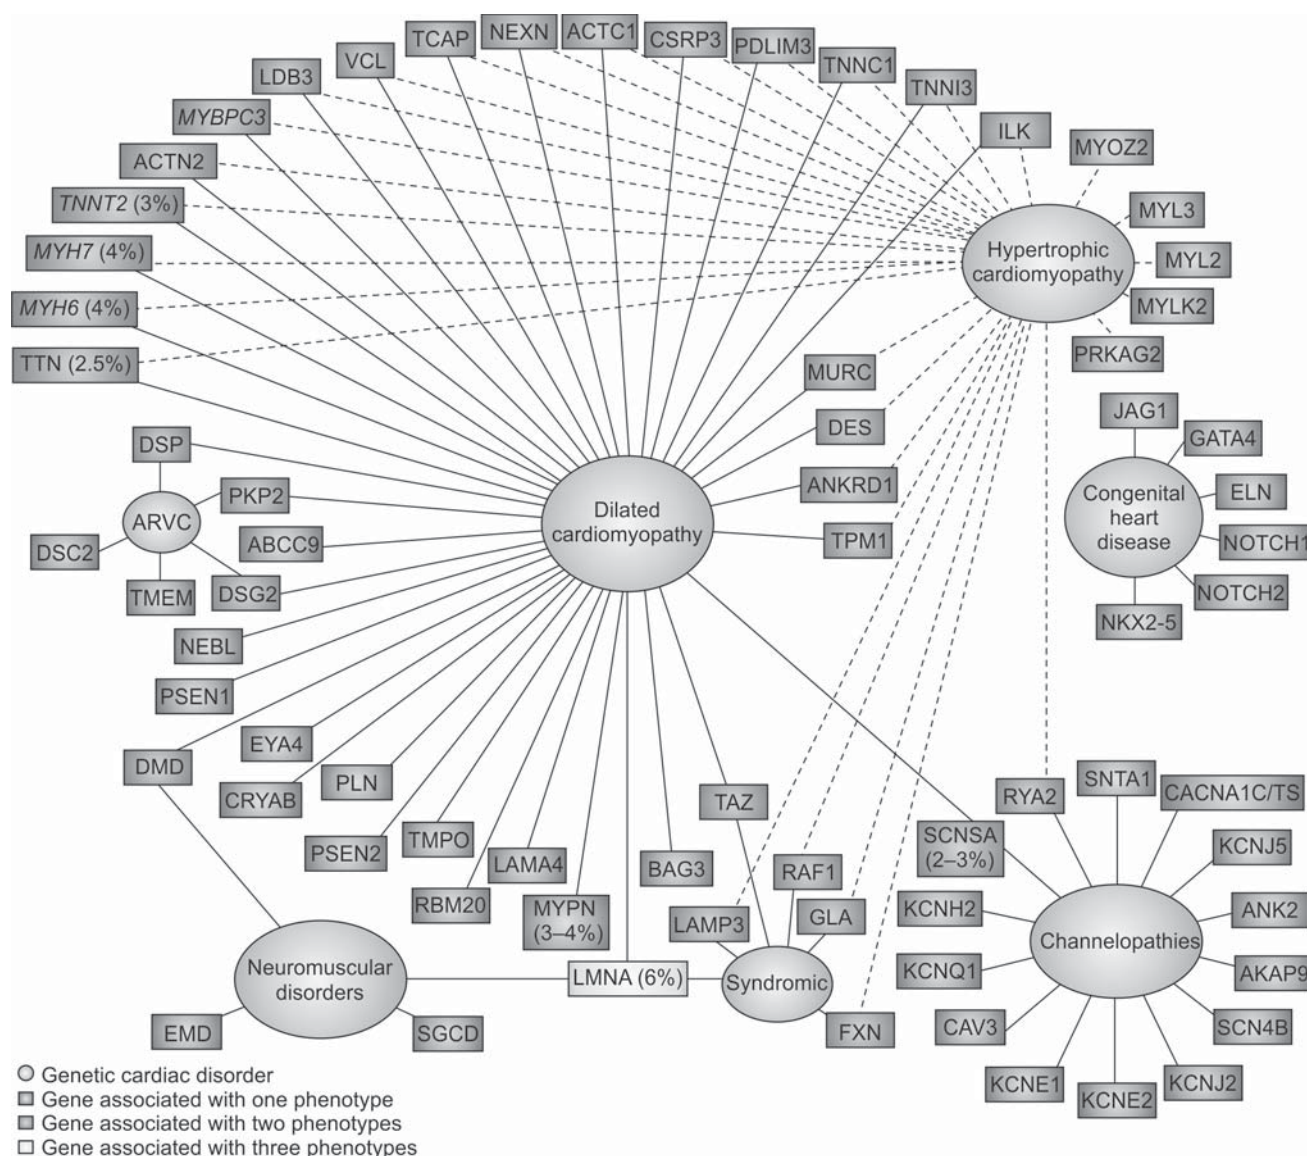

Figure 1 Various genetic mutations causing familial cardiomyopathy. The genetic architecture underlying selected genetic cardiac disorders is shown. Edges (lines) connect each phenotype to the genes that have been implicated in the etiology. Gene nodes associated with familial dilated cardiomyopathy are darker and have bold text if they have been found to cause disease in 1% of patients, and include frequency information if they have been found to cause disease in 3% of patients

[Adapted with permission of Macmillan Publishers Ltd: *Nature Reviews Cardiology*—Dilated Cardiomyopathy: the diversity of the complicated genetic architecture, copyright (2013)]

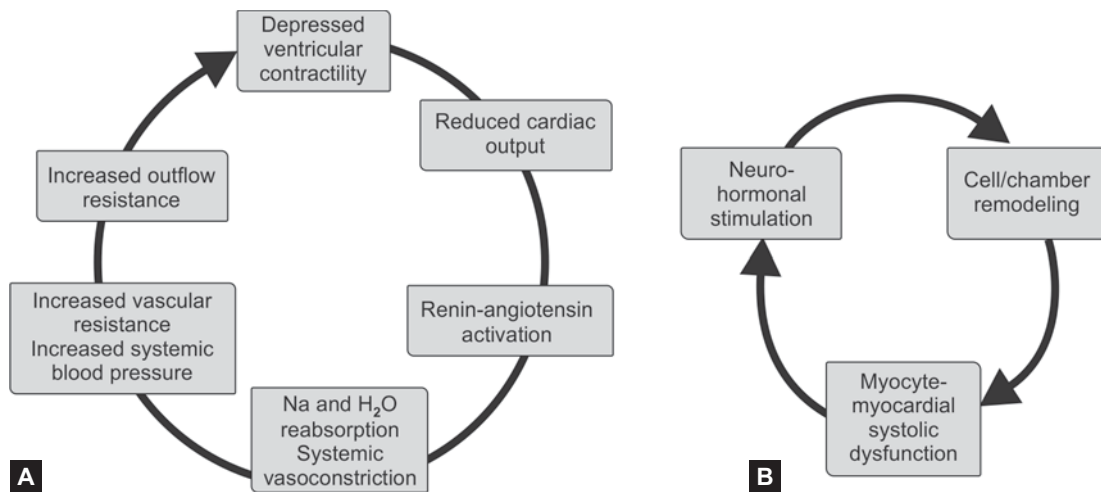

Abbreviation: ARVC, arrhythmogenic right ventricular cardiomyopathy.

from systolic anterior motion (SAM) of mitral valve and subaortic muscular hypertrophy. This obstruction is dynamic being exacerbated by reducing LV volume, lowering systemic vascular resistance and use of positive inotropic agents and improving with increasing LV volume, increasing systemic vascular resistance and use of negative inotropic agents. LV diastolic function is affected earlier than systolic function, often preserved till late. With sustained impaired diastolic function, left atrial enlargement and pulmonary venous congestion leading to congestive symptoms occur. Regional myocardial ischemia commonly occurs in HCM. This could be secondary to either increased capillary density compared to greatly increased muscle mass or small vessel disease with narrowed intramural coronary arteries. Myocardial bridge is noted in 30% of HCM which could also be the etiology of the myocardial ischemia. Right ventricular outflow tract (RVOT)

obstruction from muscle hypertrophy is not uncommon in infants and children; its infrequency in adults suggests its regression with growth.

Clinical Features

Exercise limitation is the predominant symptom in HCM. Others are dyspnea, palpitations, dizziness, chest pain or syncope. Family history is positive in 30–60% of cases. Symptomatic patients show peripheral pulses with sharp upstroke with prominent heaving LV apical thrust. The typical *late peaking* medium pitched, grade 2–3/6 systolic murmur of LVOT obstruction is heard best at mid or lower left sternal border. The murmur gets harsher with the Valsalva maneuver. The murmur of mitral insufficiency is a soft, blowing holosystolic murmur best heard at apex.

Figures 2A and B (A) Pathophysiology; and (B) Neurohumoral adaptation and its interaction with cardiac function and remodeling

Table 3 Clinical presentations of dilated cardiomyopathy

History	
<ul style="list-style-type: none"> Common presenting symptoms – Exercise intolerance – Shortness of breath – Fatigue – Syncope, near syncope – Palpitation – Loss of appetite – Feeding intolerance, poor weight gain and irritability in infants 	<ul style="list-style-type: none"> Less common presenting symptoms – Chest pain – Abdominal pain – Orthopnea – Wheezing – Chronic cough – Frothy sputum
Physical examination	
<ul style="list-style-type: none"> Systemic findings – Respiratory distress, tachypnea – Weak peripheral pulses – Low blood pressure with narrow pulse pressure – Cool extremities – Pitting edema – Hepatomegaly – Increased JVP in older children – Rales and wheezing 	<ul style="list-style-type: none"> Cardiac findings – Tachycardia – Active precordium – Displaced point of maximum impulse – Gallop rhythm – Accentuated P2 (with pulmonary hypertension) – Holosystolic murmur from mitral regurgitation

Abbreviation: JVP, jugular venous pressure.

Diagnosis

Electrocardiography (ECG) features are LVH with ST-T segment changes, deep and narrow Q waves (septal hypertrophy) in left precordial leads. Premature ventricular contractions or various degrees of heart blocks may be seen. T wave inversion in lateral leads is common in cases of apical HCM. ECG in Pompe disease may have a short PR interval. An ECG and a 24-hour Holter monitor are recommended in patients with HCM at baseline and when they become symptomatic.

Echocardiography is diagnostic in HCM, for localizing hypertrophy (LV wall 15 mm or greater in adults and $Z \geq 2$ in children) and quantifying degree of LVOT obstruction. **Figure 4** shows significant septal HCM. Peak LVOT pressure gradient of ≥ 30 mm Hg is considered as obstructive HCM. Systolic anterior motion of SAM mitral valve though commonly seen in obstructive variety however, is not specific for HCM. Left atrial dilatation and abnormal LV filling pattern indicates LV diastolic dysfunction. Systolic function of the LV is usually preserved. Characteristic *spade* deformity on echocardiographic imaging is typical of apical HCM.

Table 4 The diagnostic investigative work-up of dilated cardiomyopathy (DCM) and their findings

Chest X-ray	
Cardiomegaly, increased pulmonary vascular markings and pleural effusion (rarely)	
ECG	
Most common features	Less common features
<ul style="list-style-type: none"> Sinus tachycardia ST-T wave changes Left ventricular hypertrophy 	<ul style="list-style-type: none"> Atrial enlargements Arrhythmias (advanced cases)
Presence of deep Q waves in lead I and a VL in ALCAPA (anomalous left coronary artery from pulmonary artery) presenting as DCM	
Echocardiography	
LV: Marked enlargement with poor contractility (Figure 3) Diastolic dysfunction Mitral valve insufficiency (MV dysfunction)	Look for: Presence of pulmonary hypertension Origin and course of coronary arteries (ALCAPA)
Other tests	
Cardiac catheterization	Useful to document coronary anatomy and obtain endomyocardial biopsy
Biochemical profile	
CBC, CPK, cardiac troponin, CMP, brain natriuretic peptide (BNP) and N-terminal prohormone BNP	Helpful in risk stratification. A BNP level > 300 pg/mL was a strong predictor of death, transplantation, or heart failure hospitalization in a series of pediatric patients
Metabolic work-up	
Urine for organic and amino acids, plasma amino acids, serum lactate, and carnitine and acylcarnitine profile	
Endomyocardial biopsy	

Abbreviations: CBC, complete blood count; CPK, creatine phosphokinase.

Cardiac magnetic resonance imaging is indicated when echocardiography is inconclusive.

Cardiac catheterization though useful in assessing arrhythmia risks, obtaining endocardial biopsy and for pretransplant

Table 5 Prognosis and indicators of survival in childhood dilated cardiomyopathy (DCM)

Prognostic predictors of survival in DCM	
Poor survival	Improved survival
<ul style="list-style-type: none"> • Familial cardiomyopathy • Markedly elevated ventricular end-diastolic pressures • Presence of ventricular arrhythmias • Persistent heart failure • Tissue diagnosis of endocardial fibroelastosis coexistence of right ventricular dysfunction 	<ul style="list-style-type: none"> • Treatable causes of DCM with early detection and appropriate treatment • Improved shortening fraction over 1–6 months after presentation • Tissue diagnosis of myocarditis • Younger age

evaluation is not required for diagnostic purposes in current practice.

Genetic testing may be positive in 60–70% of patients with HCM. Genetic testing to identify mutations is recommended in a proband with HCM, atypical clinical presentation and suspected genetic condition. Patients who undergo genetic testing should also receive genetic counseling by a genetic specialist. Screening with or without genetic testing is recommended in all first degree relatives of a patient with HCM.

Sports Participation

Current practice includes at least personal history, family history and physical examination before sports participation. In the United States, use of 12 lead ECG is not included routinely in

screening process. In the presence of a positive family history of HCM or sudden death or positive genetic mutation, further testing should be considered. It may be challenging to differentiate benign physiologic hypertrophy of the athlete's heart from HCM. An athlete's heart has LV wall thickness usually 13 mm or less, LV dimensions larger than 55 mm, normal LV filling pattern and maximum oxygen consumption of more than 45 mL/kg/min (> 110% predicted) on stress test.

It is reasonable for a patient with HCM to participate in low intensity competitive sports or recreational sports. Participation in intense competitive sports is prohibited regardless of age, sex, race, presence or absence of LVOT obstruction, prior therapies for HCM or implantable cardioverter defibrillator (ICD) because of the high-risk of cardiac arrest.

Management

In symptomatic patients, management objectives of HCM are:

- To reduce ventricular contractility
- To improve ventricular compliance
- To increase ventricular volume.

Beta-blockers are the first-line agents followed by calcium channels blockers (verapamil) in those patients who are unable to tolerate beta-blockers or those with symptoms uncontrolled by beta-blockers alone. Beta-blockers improve the symptoms by negative chronotropic and inotropic effect. *Disopyramide* can be added in patients who do not respond to the earlier therapy. Propranolol is preferred for infants and children while atenolol is preferred for adolescents.

Table 6 Drug treatment of dilated cardiomyopathy in children

Agent/Drug	Comments
<i>Combined vasodilator and inotropic agents</i>	
Milrinone (PDEI)	Preferred in the hospitalized patients because of its ability to increase stroke work and thus cardiac output, decrease systemic and pulmonary vascular resistance and its unique lusitropic properties; Synergistic effects of milrinone with catecholamines may be beneficial
Levosimendan (PDEI)	Oral agent with similar properties as milrinone; no superiority over dobutamine
<i>Catecholamines</i>	
Dopamine, dobutamine	Frequently used; need for extreme caution in use: Arrhythmogenic properties and pronounced α -adrenergic effect if the patient is on β -blocker therapy
<i>Cardiac glycosides</i>	
Digoxin	Widely used in a long-term management of DCM; Improves LV contractility; not recommended in asymptomatic children with LV dysfunction; cautious use in acute HF (induces arrhythmia in inflamed myocardium; and increased toxicity in renal impairment)
<i>Diuretics: Mainstay of supportive therapy</i>	
Furosemide	Agent of choice; often, combined with weak diuretics like spironolactone to avoid hypokalemia and improve diuresis
Spironolactone	Independently shown to improve survival in patients with heart failure and should be included in long-term management
<i>Vasodilator agents: Used to decrease afterload and improve cardiac output</i>	
Nitroprusside Hydralazine	Used in acute settings
<i>ACE inhibitors: First choice for long-term use</i>	
Enalapril	Improved survival in chronic HF (multicenter study)
Angiotensin receptor blocker (ARBs)	Tried if ACEi is not tolerated due to distressing cough
<i>Beta-blockers</i>	
Carvedilol	Improves LV performance and clinical status in adults; in children, no such beneficial effect seen (RPCMCT). Despite this, beta-blockers have remained widely used in CHF

Abbreviations: PDEI, phosphodiesterase inhibitor; HF, heart failure; ACE, angiotensin converting enzyme; RPCMCT, randomized, placebo controlled multicenter trial.

Table 7 Other therapeutic modalities employed in the management of dilated cardiomyopathy (DCM)

<i>Salt and water restrictions</i>	
<i>Antithrombotic therapy:</i> Prevention and treatment of thrombus	
Antiplatelet therapy (aspirin)	Should be initiated, given the propensity for developing thrombus
Warfarin (long-term)	Aggressive treatment of thrombi if found, initially with aspirin
<i>Antiarrhythmic therapy:</i> Prevention and treatment of life-threatening arrhythmias	
Amiodarone	Used safely in children
Procainamide	To be used cautiously because of its negative inotropic effects
<i>Immunosuppressive agents:</i> Its role in DCM immunologically mediated or inflammatory myocarditis is still unproven	
Steroids, cyclosporine and azathioprine	Utility unproved in studies
Carnitine supplements	Provided, if deficiency detected
Growth hormone	Improved LV ejection fraction (in several uncontrolled studies)
<i>Mechanical circulatory supports</i>	
ECMO or VAD	May be required in acute settings or as a bridge to transplantation
Heart transplantation	Consider those children with DCM who are refractory to medical therapy, VAD dependent or requiring frequent inotropic support and whose likelihood of short-term survival is unfavorable
<i>Prevention of sudden cardiac death (SCD):</i> SCD incidence is about 1% of children with DCM	
Use of ICDs	May not be justified for primary prevention; well accepted for secondary prevention
Cardiac resynchronization	Needs further evaluation in pediatric population

Abbreviations: ICD, implantable cardioverter defibrillator; ECMO, extracorporeal membrane oxygenation; VAD, ventricular assist device.

**Figure 3** Four-chamber view of echocardiogram in dilated cardiomyopathy (DCM) its interaction with cardiac function and remodeling

Calcium channel blockers should be avoided in children less than 1 year of age. Specific antiarrhythmic medications should be used for documented arrhythmias. Anticoagulation and ventricular rate control medications are indicated in patients with paroxysmal, persistent or chronic atrial fibrillation with HCM.

Inotropic agents and vasodilators are contraindicated in obstructive HCM. In acute hypotension, pure vasoconstrictors such as phenylephrine should be used. Diuretics are generally avoided because they can be harmful by depleting LV volume however, in severe secondary heart failure, they can be used judiciously to relieve congestive symptoms.

Surgical myomectomy should be considered in a symptomatic children with LVOT gradient of more than 50 mm Hg and failed medical management.

Other forms of therapies such as *alcohol septal ablation*, *dual chamber pacemaker* or *mitral valve replacement* have not been routinely performed in children with HCM. Consideration for *heart transplantation* may be required in certain selected cases such as refractory arrhythmia or children with HCM and restrictive physiology and advanced heart failure that are not responsive to other therapeutic interventions.

Medical management can offer symptomatic relief; however it cannot reduce the risk of sudden death or heart failure. ICDs have been shown to reduce the incidence of sudden cardiac death (SCD).

Risk factors for sudden death includes prior history of ventricular tachycardia, ventricular fibrillation or aborted SCD, unexplained syncope LV thickness of more than or equal to 30 mm, abnormal blood pressure response during exercise (failure to rise by at least 20 mm Hg or a drop of at least 20 mm Hg at peak exercise) and family history of SCD. All patients with HCM should undergo comprehensive SCD risk stratification in order to determine the need for ICD placement.

Affected individuals should be restricted from moderate to high intensity competitive sports. Comorbidities like hypertension, diabetes, hyperlipidemia or obesity should be treated.

Follow-up Visits

Frequent follow ups with ECG, echocardiogram and/or a 24-hour Holter monitor (12–18 months in children and adolescents) are required for asymptomatic children to monitor for LVOT obstruction, presence of arrhythmia and degree of progression of hypertrophy.

Prognosis

Hypertrophic cardiomyopathy with a diverse clinical presentation and course has annual mortality rate which is slightly higher in children compared to adults (2% vs. 1% per year). Most patients with HCM may also have normal life expectancy. Difficulty in predicting outcome in children with HCM is inherent for such a heterogeneous disease over long periods.

Several other conditions manifest with LVH and mimic typical HCM caused by sarcomere protein mutations as described in **Table 8**. Long-term prognosis in the infant with HCM and metabolic disease is poor.

RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy (RCM) is a rare form of chronic heart disease characterized by normal or decreased volume of both ventricles associated with biatrial enlargement, normal left ventricular wall thickness and AV valves, impaired ventricular filling with restrictive physiology and normal (or near normal) systolic function.

Figure 4 Echocardiography of hypertrophic cardiomyopathy

Table 8 Inherited form of hypertrophic cardiomyopathy (HCM) from nonsarcoplasmic mutations

Conditions	Gene/enzyme	Inheritance	Clinical features	Prognosis
Noonan syndrome	<i>PTPN11</i> mutation	Autosomal dominant	LV hypertrophy, dysplastic pulmonary valve stenosis and atrial septal defect	Good
Fabry disease	α -galactosidase A deficiency	X-linked recessive	Angiokeratomas, corneal clouding, peripheral neuropathy, renal failure, anhydrosis	Poor unless treated with enzyme replacement therapy
Pompe disease	α -1,4 glucosidase deficiency	Autosomal recessive	HCM, hypotonia, hepatomegaly, ECG: short PR interval, biventricular hypertrophy	Death before 2 years unless received enzyme therapy
Danon disease	<i>LAMP2</i> gene mutation	X-linked semi-dominant	Cardiomyopathy, intellectual disability, skeletal muscle weakness	Poor
Others	<i>PRKAG2</i> mutation	Autosomal dominant	Progressive LVH, conduction system abnormalities, proximal myopathy	Poor

Abbreviation: LVH, left ventricular hypertrophy.

Epidemiology and Genetics

Restrictive cardiomyopathy in children represents 2.5–5% of all diagnosed cardiomyopathies. In children, the average age of diagnosis is 6 years. The frequency of RCM in both sexes is similar. The family history is positive in 30% of children. At least 10 genetic mutations have been found to be associated with RCM phenotype. Sarcomeric protein mutations have been described in troponin I, troponin T, α -cardiac actin, MYBPC and β -myosin heavy chain. Nonsarcomeric mutations in genes coding for proteins such as like desmin, RSK2 (Coffin-Lowry syndrome), lamin A/C (Emery-Dreifuss) and transthyretin have been described.

Etiology

Restrictive cardiomyopathy can be caused by multiple etiologies as given in **Table 9**. In tropical countries, endomyocardial fibrosis (EMF) is considered to be the most common cause of RCM. Outside of the tropics, idiopathic RCM is the most common cause, followed by anthracycline toxicity.

Pathophysiology

In RCM, ventricular chamber dimensions, wall thickness and systolic function are usually preserved. Most ventricular filling occurs in rapid filling phase with little or no filling in late diastole. Because of the stiff ventricular walls, ventricular filling pressures are increased, leading to marked atrial dilation. This ultimately leads to pulmonary and/or systemic venous congestion. Coronary ischemia may also be encountered in this population. A possible mechanism of ischemia could be diffuse hypoperfusion of the

subendocardial myocardium from impaired coronary perfusion secondary to high ventricular filling pressure rather than coronary anomalies per se.

Clinical Features

Children with RCM usually present with respiratory symptoms. With left ventricular involvement, cough, dyspnea, chest pain, exercise intolerance or syncope may occur. Syncope occurs in about 10% of this population and could be secondary to thromboembolism, ischemia or arrhythmias. With right ventricular involvement, lower limb edema, hepatomegaly and ascites may occur.

Physical examination may reveal jugular venous distension, loud P_2 (from pulmonary hypertension) and systolic murmur from AV valve insufficiency. Crackles in lungs, hepatomegaly, ascites, and edema are also common findings in advanced disease.

Diagnosis

Chest X-ray is usually positive for cardiomegaly from enlarged atria, pulmonary venous congestion and occasionally pleural effusion.

ECG demonstrates typical left and right atrial enlargements with peaked P waves. ST-T wave changes and ST segment depression is seen frequently. Arrhythmias/conduction disturbances have been found in 15% of pediatric patients with RCM and therefore, a 24-hour Holter monitor is recommended to diagnose occult arrhythmia.

Echocardiography is the corner stone of diagnosis. Marked atrial dilation is easily identifiable. Ventricular systolic function is usually preserved; however, in severe cases LV dysfunction may be

Table 9 Etiology of restrictive cardiomyopathy

Idiopathic
Familial/genetic
Storage disorders—Hurler syndrome, Gaucher disease, Fabry disease, glycogen storage diseases
Endomyocardial—endomyocardial fibrosis, hypereosinophilia syndrome (HES), endomyocardial fibroelastosis, carcinoid
Infiltrative disorders—hemochromatosis, amyloidosis, sarcoidosis, cystinosis, fatty infiltration, metastatic cancers
Myocarditis
Radiation
Post-heart transplant
Drugs—anthracycline, serotonin, methysergide, ergotamine
Scleroderma
Genetic syndromes—Emery-Dreifuss syndrome, Coffin-Lowry syndrome

present. Although ventricular wall dimensions are normal in the majority of the cases, it is not unusual to find various degrees of hypertrophy. This may be true particularly for the subset of patients with troponin I mutation. In EMF, AV valves can also be involved, leading to thickened valve leaflets and decreased excursions. The presence of thrombus and pulmonary hypertension should always be looked for. Pericardial thickening may direct the diagnosis towards constrictive pericarditis rather than RCM. Abnormal Doppler indices suggest LV diastolic dysfunction.

Cardiac catheterization is indicated at the time of the diagnosis to document detailed hemodynamics. A classic early diastolic dip followed by a plateau pattern known as a *square root sign* is noted on catheterization. Cardiac catheterization is also helpful in differentiating RCM from constrictive pericarditis (CP) which is a readily treatable disease.

Management

The therapy is mostly supportive and directed towards relieving symptoms. Diuretics though helpful in abating congestive symptoms must be carefully used; over-diuresis is avoided because of the sensitivity of these patients to preload. Antiplatelet and/or anticoagulation therapies should be considered for all patients. ACE inhibitors reduce systemic vascular resistance without increasing cardiac output in RCM and thus are not beneficial. The role of beta-blockers in children with RCM has not been studied. Arrhythmias should be treated accordingly. Some children may require a pacemaker for complete heart block. Pulmonary hypertension eventually occurs in all patients. It is treated with oral or IV pulmonary vasodilators. Cardiac transplantation is the only definitive therapy currently available. Early transplantation is preferable before pulmonary hypertension ensues.

Prognosis

The prognosis of RCM is generally poor with an annual mortality rate of 7%. The 2-year mortality rate is as high as 50%. Sudden death has been reported from 14% to 33% in children with RCM. Poor prognostic factors have not been well-defined in children.

OTHER CARDIOMYOPATHIES

Arrhythmogenic Right Ventricular Cardiomyopathy/Dysplasia

Arrhythmogenic right ventricular cardiomyopathy (ARVC), often inherited as an autosomal dominant cardiomyopathy,

is characterized by right ventricular (RV) myocyte loss with fibrofatty replacement that predisposes the child to increased risk of ventricular arrhythmias and sudden death. It is more common in Europe, especially Italy. Mutations in desmoplakin (DSP), *plakophilin-2*, and *desmoglein-2* and *desmocollin-2* genes are observed. Naxos disease with mutations in plakoglobin (palmoplantar keratoderma and woolly hair) and Carvajal syndrome (mutation in desmoplakin,) are two recessive forms with this type of cardiomyopathy. Possible infection/inflammatory process by coxsackievirus B13 and adenovirus have been implicated. Fatty and fibrofatty replacement of the RV myocardium leads to thinning of the wall, aneurysms, RV dilatation and regional/global RV dysfunction. Involvement of LV may also occur. The essential details are given in the **Table 10**.

Left Ventricular Noncompaction

Left ventricular noncompaction (LVNC), described as a primary genetic cardiomyopathy due to mutations on at least nine different genes, is characterized by an abnormal (spongy) myocardium with prominent trabeculae and deep intertrabecular recesses communicating with the LV cavity and resulting into two distinct layers comprising compacted and noncompacted myocardium. A maturational arrest in the process of normal compaction during fetal life is the postulated mechanism. Sporadic cases have also been reported. The disease is progressive with worsening of LV function, arrhythmias and thromboembolic complications. Treatment is directed towards anticongestive measures, antiarrhythmic therapy and antiplatelet or anticoagulation therapy. Cardiac transplantation may also be considered in selected patients who are refractory to medical therapy. The essential details are given in the **Table 11**.

Asymmetric Septal Hypertrophy in Infants of a Diabetic Mother

Asymmetric hypertrophy with pronounced septal involvement compared to the ventricular free walls is more commonly observed in infants of a diabetic mother (IDMs) besides other congenital heart defects. The overall incidence of LV hypertrophy is 10–20%. Hyperinsulinemia leads to the ventricular hypertrophy during fetal life. This is a special group with the highest incidence of regression of LV hypertrophy. These infants are macrosomic, plethoric and may have tachypnea and/or tachycardia. Congestive heart failure may develop in 5–10% of affected infants. Echocardiogram shows LVH with or without obstruction. Beta-blockers are the mainstay of treatment in the obstructive variety. In severe heart failure, pure alpha agonists such as phenylephrine should be used to maintain blood pressure. Typically, ventricular hypertrophy regresses within the first few months of life.

Cardiomyopathy in Duchenne Muscular Dystrophy

Duchenne muscular dystrophy (DMD), transmitted in X-linked recessive fashion, is caused by the defect of the dystrophin gene leading to absence of dystrophin. Dystrophin is present in skeletal muscles, cardiac muscles, neurons and smooth muscles. It is the most common muscular dystrophy in children with an incidence of 30 per 100,000 livebirths. Absence of dystrophin makes cell membrane vulnerable to injury resulting into endomysial fibrosis. Skeletal muscles are primarily affected leading to respiratory compromise.

Cardiomyopathy is invariably associated with DMD. In advanced cases, symptoms of heart failure such as dyspnea, orthopnea and edema may occur. Symptoms are often inseparable from the respiratory dysfunction. The earliest sign of affected cardiac function is unexplained tachycardia that does not change

Table 10 Arrhythmogenic right ventricular cardiomyopathy/dysplasia (ARVC)

Estimated prevalence	1 per 5,000
Usual age of onset of symptoms	20 years of age and beyond
Clinical features	Palpitations, syncope, arrhythmias—ventricular tachycardia (VT), sudden cardiac death (SCD)
Diagnosis*	
ECG	Epsilon waves (undulation in the ST segment indicative of postexcitation low amplitude potential), T wave inversion in V1-V3 (important between ages 19 and 45) and prolonged S wave stroke. Left bundle branch morphology is more common and seen with tachycardia
Echocardiography	Enlarged and thin RV with decreased regional/global systolic performance
MRI (diagnostic)	Global and regional ventricular dilation, global and regional ventricular dysfunction, intramyocardial fat, focal wall thinning and late gadolinium enhancement
Cardiac catheterization	Resorted to: (1) to obtain hemodynamic information, and (2) to obtain endocardial biopsy
Management	
To prevent sudden cardiac death	Implantation of ICD: Warranted as primary preventive measure in high-risk patients. Definitely indicated for secondary prevention
To decrease the frequency of sustained VT episodes	Catheter ablation
To reduce the frequency of arrhythmia	Beta-blockers—its use, however, may not reduce the risk of sudden cardiac death

Abbreviation: MRI, magnetic resonance imaging.

*Diagnostic criteria have been published recently and reference can be found in the *More on this topic*.

Table 11 Left ventricular noncompaction (LVNC)

Onset of symptoms	Only at late age
Primary symptoms and signs	Symptoms of heart failure
Other findings	Neurological disorders in about one-third
Differential diagnosis	Metabolic myocardial diseases especially mitochondrial disorders and Barth syndrome (<i>Tafazzin</i> gene mutation) must be excluded
Diagnostic investigations	
ECG	Giant QRS complexes, T wave changes and WPW pattern
Echocardiography	Diagnostic; thin compacted and thick noncompacted regions of the myocardium with visible trabeculations. LV involvement can be segmental involving predominantly apical segment of LV or global; ratio of compacted to total (noncompacted + compacted myocardium) during diastole less than 0.5 is diagnostic
Cardiac MRI (Figure 5)	Considered when echocardiography is inconclusive; ratio of noncompacted to compacted myocardium more than 2.3 is diagnostic

Abbreviation: MRI, magnetic resonance imaging.

with increasing age. This is thought to be from an increased sympathetic response to ventricular dysfunction. ECG may also demonstrate pathologic Q representing myocardial scarring or infarct. Other conduction abnormalities such bundle branch block and heart block may be present secondary to involvement of Purkinje system. Fatal ventricular arrhythmias can occur in severe ventricular dysfunction.

Echocardiography demonstrates inappropriately reduced LV wall thickness and increased LV dimensions. Ventricular systolic function is affected first and commonly present after 10 years of age. The degree of ventricular systolic dysfunction and skeletal muscle dysfunction do not correlate. No specific treatment is

**Figure 5** Cardiac magnetic resonance (CMR) of left ventricular noncompaction (4-chamber view)

available to halt the progression of cardiac dysfunction. Treatment is directed towards relieving heart failure symptoms. Therapies aimed at decreasing fibrosis such as immunosuppressants including steroids have been shown to improve muscle strength in DMD. Care should be taken in subjecting these patients to any type of surgery as anesthetic complications such as hyperthermia, cardiac arrest or rhabdomyolysis are more prone to occur in the presence of cardiac dysfunction. In high-risk patients with severe ventricular dysfunction, only emergent surgical procedures should be undertaken. DMD patients have an average survival of 20 years or less, with respiratory compromise being the primary reason for death.

Anthracycline Induced Cardiomyopathy

Doxorubicin (anthracycline), used as chemotherapeutic agents in several childhood cancers, has been shown to affect heart function due to its ability to generate reactive oxygen species causing lipid

peroxidation of the myocyte cell membrane and subsequent cell injury. Anthracycline induced cardiomyopathy exhibits in different phases: acute phase—symptoms within 1 week of treatment, occurs very rarely; early-onset—symptoms occurring within 1 year; and late-onset—symptoms occurring after 1 year. Clinical heart failure, decreased exercise capacity and arrhythmias are common. Clinical congestive heart failure correlates with total cumulative dose. Although there is no safe dose of doxorubicin, a total cumulative dose of less than 300 mg/m² is hardly associated with significant adverse effect on LV contractility. Symptomatic heart failure is seen in 2–5% of patients at doses of 400–500 mg/m². Elevated cardiac troponin-T and N-terminal pro-brain natriuretic peptide within 90 days of treatment were associated with abnormal LV structure and function at 4 years after diagnosis may suggest their usefulness in monitoring disease progression.

Modifiable risk factors include obesity, dyslipidemia, metabolic syndrome, type-2 diabetes, mediastinal radiation, total cumulative dose, hypertension, and treatment with cyclophosphamide, paclitaxel, or trastuzumab. **Nonmodifiable risk factors** include younger age (especially < 4 years), female gender, trisomy 21, African-American ethnicity, and genetic mutation of the *HFE* gene associated with hereditary hemochromatosis.

Prevention

Limiting the total cumulative dose to less than 300 mg/m² has been suggested. Structurally modified anthracyclines such as epirubicin or idarubicin and liposomal derivatives of anthracycline to reduce cardiotoxicity can be tried. Cardioprotection from agents that reduces production of free oxygen radicals such as dexrazoxane has brought promising results. Other antioxidants such as N-acetyl cysteine, vitamin E, L-carnitine and coenzyme-Q have been tried with variable success. Carvedilol also has mild antioxidant effect besides being a beta-blocker. Amifostine, a selective cardioprotector, as demonstrated in rat studies, does not interfere with the antineoplastic action of anthracyclines.

Treatment

The general consensus is to discontinue anthracycline therapy with the onset of clinical heart failure. ACE inhibitors and beta-blockers have been shown to be of benefit in halting the progress of LV dysfunction in idiopathic cardiomyopathy; however, their benefit is unproven in anthracycline-induced cardiomyopathy. Growth hormone therapy is still in experimental phases with potential of short-term benefit.

Prognosis

It is generally poor if clinical heart failure sets in. Cardiac transplantation may be beneficial in the long-term if probability of tumor recurrence is low.

IN A NUTSHELL

1. Myocardial diseases, inherited or acquired, constitute a major cause of cardiovascular morbidity and mortality in children.
2. Myocarditis is an inflammatory disease of the myocardium and the most common known cause of dilated cardiomyopathy in children.
3. Dilated cardiomyopathy is the most common form of cardiomyopathy in children which is characterized by the ventricular dilation and systolic dysfunction resulting into congestive heart failure.
4. Hypertrophic cardiomyopathy, a genetically inherited disease, is associated with ventricular hypertrophy and represents the most common cause of sudden death in adolescents and young adults.
5. Restrictive cardiomyopathy is a rare cardiomyopathy and has poor prognosis.
6. Treatment includes management of heart failure symptoms and prevention of arrhythmia, thromboembolic complications and sudden death.
7. Heart transplantation is the therapy of choice for end-stage cardiomyopathies refractory to medical therapy.

Chapter 40.36

Diseases of the Pericardium

Manoj Kumar Rohit, Ankur Gupta

Pericardium, a double layered structure consists of inner serosal visceral pericardium adhering to the myocardium and an outer fibrous parietal pericardium consisting of elastic fibers and collagen. About 30 mL of pericardial fluid in this space lubricates the heart during its contraction. Its blood supply is from the internal mammary arteries and the descending aorta. It is innervated by the vagus, phrenic and sympathetic fibers.

ETIOLOGY

The causes of pericardial diseases are (**Table 1**):

- Infectious,
- Noninfectious, and
- Congenital.

Table 1 Causes of pericarditis and pericardial diseases in children

Infectious	
Viral	Echovirus, coxsackievirus, adenovirus, influenza, cytomegalovirus
Bacterial	<i>Haemophilus influenzae</i> , <i>Streptococcus</i> , <i>Staphylococcus</i> , gram-negative organisms
Mycobacterial	<i>Mycobacterium tuberculosis</i> , <i>Mycobacterium avium-intracellulare</i>
Fungal	<i>Histoplasma</i> , <i>Candida albicans</i>
Protozoal	<i>Toxoplasma</i> , <i>Echinococcus</i>
Noninfectious	
Connective tissue disorders	Acute rheumatic fever, rheumatoid arthritis, systemic lupus erythematosus, mixed connective tissue disorders, systemic sclerosis
Metabolic	Nephrogenic, hypothyroidism, Gaucher disease
Traumatic	Surgery, blunt and penetrating trauma
Neoplastic	Primary and secondary (leukemia, lymphoma)
Congenital	
Cysts, absence of pericardium, Mulibrey nanism	

ACUTE PERICARDITIS

Clinical Features

Acute pericarditis is a syndrome characterized by chest pain, pericardial friction rub and electrocardiographic changes. Child gives history of retrosternal pain often radiating to the trapezius ridge and which increases on lying down and in inspiration and decreases with sitting posture. Pericardial friction rub has a superficial, scratchy character and may be heard anywhere over the precordium. A monophasic rub is confined to ventricular systole, biphasic includes atrial systole and triphasic rub includes ventricular diastolic filling.

Electrocardiographic Changes

The PR, ST-T wave changes in the electrocardiograph (ECG) are diffuse and may confirm the clinical suspicion of pericarditis. Characteristics findings on the ECG include PR depression in all the leads except aVR and ST elevations (concave upwards and < 5 mm elevation; **Figure 1**) which is followed by the settling of the ST elevations and subsequently T wave inversions with complete normalization of the ECG in a typical 2 weeks period. However, only 50% patients display all ECG changes. Close differential diagnosis are acute myocardial infarction and early repolarization variant. Unlike adult myocardial infarction does not occur in young children except in case of *anomalous origin of left coronary from pulmonary artery* which has typically lateral wall infarct (Q waves with T wave inversion in lead I, aVL and V4-V6 on ECG) and picture of significant left ventricular systolic dysfunction.

Diagnosis

The aim of imaging and laboratory studies is to find the etiology of acute pericarditis. It includes chest X-ray, detailed ECG and blood markers of inflammation including erythrocyte sedimentation rate (ESR) and white blood cell count. An extensive evaluation is generally not required in a healthy child in whom pericarditis is preceded by a viral prodrome as such patients have a self-limiting course. Etiological factors like trauma, myocarditis, systemic lupus erythematosus (SLE) and purulent pericarditis should be considered in children if history or any clinical features suggest.

Treatment

Primary treatment is for the underlying etiology. Antibiotics remain the mainstay for bacterial infections. Acute pericarditis of noninfectious origin usually responds to nonsteroidal anti-inflammatory drugs (NSAIDs) like acetylsalicylic acid or ibuprofen.

Figure 1 Electrocardiograph (ECG) of a patient with acute pericarditis showing PR depression in all the leads except aVR and diffuse, nonspecific, concave ST segment elevations

In adults, colchicines either as a supplement to NSAIDs or as monotherapy especially in recurrent cases (20–50% patients) is also effective. Experience of colchicines use in children is limited to be recommended for use at this stage. Some cases, particularly of connective tissue disease or uremic pericarditis, may require steroid treatment (prednisolone 1 mg/kg/day) for a week which may be tapered on an individual basis.

SPECIFIC FORMS OF PERICARDITIS

Viral Pericarditis

It is the most common form of pericarditis in children, though more often viral infection is presumed rather than proved. Around 50% children present with viral prodrome, with pericardial friction rub being present in up to 80% patients. Viral isolation from pericardial fluid or viral polymerase chain reaction (PCR) in pericardial fluid or a rise in the viral neutralizing antibodies in the acute and convalescent phase serum is done for a definitive diagnosis. Treatment remains symptomatic with bed rest and NSAIDs. Steroid therapy is rarely indicated.

Bacterial Pericarditis

Etiology and Risk Factors

Bacterial pericarditis is frequently caused by streptococci, staphylococci, and gram-negative organisms with *Haemophilus influenzae* being an important cause in children. *Staphylococcus aureus* is the most common causative agent in our settings. Predisposing factors are immunosuppression, chronic diseases, cardiac surgery and trauma.

Clinical Features

The typical features of pericarditis are usually absent and the course is fulminant with rapid progression to cardiac tamponade. Such patients usually have widespread systemic infection and sepsis and pericarditis is often missed.

Management

Diagnosis is made on echocardiography and purulent effusion should be drained and appropriate antibiotics should be started. Pericardial window should be created for recurrent or nonrelapsing effusions. Pericardiectomy is required for dense adhesions, loculated effusions, recurrent tamponade and in patients who develop constrictive pericarditis. Acute bacterial pericardial effusion generally requires drainage either by surgery or percutaneously along with antibiotics. In centers where facility for cardiac surgery is not available, intrapericardial instillation of streptokinase by dissolving the fibrinous components of the exudates is thought to be helpful.

Outcome

Mortality despite treatment remains high (around 40%).

Tubercular Pericarditis

Tuberculosis remains the most important cause of pericarditis, both in the adults and in children, in India. Its incidence is increasing because of human immunodeficiency virus (HIV) infection. Tubercular pericarditis is a delayed hypersensitivity response to the antigens of the tubercular bacilli which enters the pericardium either directly from the infected mediastinal lymph nodes or through the hematogenous route. Typical symptoms of pericarditis like pain and pericardial friction rub are absent and the child presents with chronic symptoms of fever, decreased appetite, weight loss and night sweats. An acute phase of inflammation progresses finally in constriction in about 50% patients.

Management

Definitive diagnosis of tubercular pericarditis on the basis of histological examination and culture of *Mycobacterium tuberculosis* is difficult. Indirect diagnostic tests like PCR detected *M. tuberculosis* DNA and elevated levels of adenosine deaminase, lysozyme and interferon gamma in pericardial fluid are more helpful in clinical settings. Patients with tubercular pericarditis should be treated with a regimen of isoniazid, rifampicin, pyrazinamide and ethambutol for 2 months and continued on isoniazid and rifampicin for further 4 months. Corticosteroids (prednisolone 1 mg/kg/day) may be given for initial 2 months and benefits by reducing morbidity and mortality, but definitive data regarding lack of progression to constrictive pericarditis is lacking. As around 50% patients develop constrictive pericarditis, they will require pericardiectomy.

Noninfectious Pericarditis

Pericarditis may be present in any connective tissue disorder and presents as acute or chronic pericarditis with or without effusion. Pericardial involvement in acute rheumatic fever is seen in about 10% patients and occurs as a part of pancarditis. It is not associated with increased mortality and is treated with NSAIDs. Symptomatic pericarditis occurs in about 10% children with juvenile rheumatoid arthritis and in 25% children with SLE, though asymptomatic pericardial involvement diagnosed on the basis of echocardiography occurs in up to 50% patients. Treatment is with NSAIDs accompanied with a short course of steroids.

Pericarditis in renal failure is associated with uremia. Patients are usually asymptomatic and may present with large pericardial effusion of even cardiac tamponade. Treatment involves NSAIDs and intensification of dialysis. Cases of resistant or recurrent effusions require drainage or even pericardial window or pericardiectomy.

Pericardial effusion is seen in up to 33% patients with myxedema. The patients are not much symptomatic due to pericarditis and present with bradycardia. The effusion develops slowly and responds to thyroid supplementation. Pericardial tamponade is rare. And hence in cases of idiopathic pericardial effusions besides routine test thyroid stimulating hormone (TSH), antinuclear antibody (ANA) should also be done regularly.

CONGENITAL PERICARDIAL DISEASE

Pericardial Cysts

Pericardial cysts are formed due to defective embryological development of the pericardium. These are usually benign and are incidentally detected in an asymptomatic patient on a chest X-ray. Though they can be present in hilar or mediastinal location but are most commonly found in right costophrenic angle. A computed tomography (CT) chest can be done to help differentiate from a neoplasm. Usually no treatment is required.

Congenital Absence of Pericardium

Congenital absence of the pericardium is a rare anomaly which may involve a part or whole of the pericardium. Left side defects are much more common than the right side. Mostly the patients are asymptomatic and are diagnosed when a chest X-ray reveals leftward displacement of the heart border. Some patients may be symptomatic with chest pain, syncope and even sudden death which may be related to herniation of the left atrial appendage or torsion of the great vessels. Congenital heart and pulmonary anomalies are present in 30% patients. ECG is either normal or shows incomplete right bundle branch block. Echocardiography reveals a dilated right ventricle and paradoxical septal motion. Magnetic resonance imaging (MRI) and CT are confirmative

diagnostic tests. Size of the pericardial defect dictates the need for surgical treatment. Complete absence and very small defects do not need any treatment. The defects in the patients with risk of cardiac herniation are either closed by patch closure or enlarged to prevent incarceration.

CONSTRUCTIVE PERICARDITIS

Constrictive pericarditis is uncommon in children. It is characterized by a thickened and scarred pericardium due to acute or chronic pericardial inflammation. Diastolic filling of the ventricles is compromised. Tuberculosis is responsible for majority of cases. Other rare causes are cardiac surgery, radiation therapy, renal failure and connective tissue diseases.

Clinical Features

Signs and symptoms include fatigue, dyspnea, weight gain, abdominal distension and pedal edema. Examination shows pedal edema, prominent y and deep x descents in jugular veins, ascites and hepatosplenomegaly. Arterial blood pressure is usually normal. Kussmaul sign, which is failure of the venous pressure to decrease with inspiration, though not specific, is commonly seen. Diastolic pericardial knock, which is similar in timing to the third heart sound, corresponds to the abrupt cessation of the ventricular filling and is pathognomonic.

Diagnosis

Electrocardiography shows low voltage QRS complexes, T wave changes and is nonspecific. Chest X-ray shows pericardial calcification in less than half of these patients (**Figs 2A and B**). Pleural effusion may be present with normal or enlarged cardiac silhouette depending upon the extent of pericardial effusion. Echocardiography may demonstrate pericardial thickening and some pericardial effusion. Important 2D-echocardiography findings include a jerky interventricular septum, dilated inferior vena cava without respiratory variation and biatrial enlargement with normal left ventricular ejection fraction. Important Doppler echocardiography findings include decreased mitral inflow velocity with increased tricuspid inflow velocity in the first beat after inspiration and increased hepatic vein flow reversal in

expiration suggesting ventricular interdependence. Doppler tissue imaging shows a prominent E and gives an important point of distinction from restrictive cardiomyopathy. CT and MRI are sensitive investigations for determination of pericardial thickness and also help in differentiating from restrictive cardiomyopathy.

Cardiac catheterization with a predictive accuracy of around 75% is often done to confirm the diagnosis and exclude restrictive cardiomyopathy. It shows equal and elevated left and right atrial pressures, pulmonary capillary wedge pressure and ventricular end-diastolic pressures (usually more than one-third of right ventricular systolic pressure). A characteristic square root sign and discordance between right and left ventricular peak systolic pressures with respiration (right ventricular systolic pressure increases and left ventricular systolic pressure decreases during inspiration and vice-versa) are seen in the diastolic ventricular tracings.

Treatment

Pericardiectomy is the treatment of choice. Complete pericardial resection is recommended to prevent recurrences. Operative mortality is around 6% and is improving. Advanced age, higher New York Heart Association (NYHA) class and postirradiation etiology are poor prognostic factors.

IN A NUTSHELL

1. Viral pericarditis is the most common cause of acute pericarditis in children. Other less common causes are trauma, myocarditis, systemic lupus erythematosus (SLE) and purulent pericarditis.
2. Bacterial pericarditis usually occurs due to staphylococcal and *Haemophilus* infections. Appropriate antibiotics with urgent drainage of pericardial space are the standard of care. Some children would require surgical pericardiectomy.
3. Tubercular pericarditis is an important cause of constrictive pericarditis in India.
4. Noninfectious causes of pericardial involvement include systemic lupus erythematosus, rheumatic fever, systemic onset juvenile idiopathic arthritis, uremia and hypothyroidism.

Figures 2A and B (A) Lateral chest X-ray showing pericardial calcification in a patient of chronic constrictive pericarditis; (B) Computed tomography (CT) of chest showing pericardial and atrioventricular groove calcification in the same patient

Chapter 40.37

Cardiac Dysrhythmias

Ramandeep S Ahuja, Rajnish Juneja

Cardiac dysrhythmias (arrhythmias are not an appropriate term as it implies absence of rhythm; however like so many other things it is unlikely to change) are no longer a subject that can be left to the cardiologists or the internists. Basic electrocardiographic (ECG) skills along with identification and management of common cardiac arrhythmias are essential for the pediatrician also.

Arrhythmias can occur in a variety of settings, acute or chronic, and present in several different ways. The worst presentation is sudden cardiac death (SCD) in a child who is otherwise completely healthy or has been leading a perfectly normal life post correction of a congenital heart defect, suddenly drops dead. Arrhythmias, we know can occur in normal hearts—diseases like long QT Syndrome (LQTS) and Brugada syndrome are seen all over the world with the same penetration. This chapter is focused on providing the reader a basic idea of how, what and where arrhythmias should be suspected and managed.

ARRHYTHMIAS ARE OMNIPRESENT

Arrhythmias can present in diverse ways—the simplest and most usual is a child complaining of something going wrong in his chest and when the parents put a hand on the chest they find the heart racing away. Obviously a child who has not reached the age to converse will not complain and maybe completely asymptomatic or crying inconsolably. A totally reverse situation is when we go hunting for an arrhythmia—to us it is imperative that every child on treatment for seizures should have an ECG done and history taking probe into similar events in other sibs. Every year we see at least one or two patients being treated for *refractory epilepsy* to be having a *channelopathy* like LQTS. Similarly, every child diagnosed as dilated cardiomyopathy (DCM) should have an ECG, because tachycardia related left ventricular dysfunction (tachycardiomyopathy [TCMP]) is among the treatable causes for an otherwise untreatable disease (**Box 1**: Case Vignettes). These examples emphasize on the need for constant improvement in our skills and abilities. We hope this chapter serves as a stimulus for pediatricians to sharpen their ECG skills.

BOX 1 Case Vignettes

Case Vignette 1

A 2-year-old child, with dilated cardiomyopathy with an ejection fraction of 15%, on routine medical management for over 6 months, was seen in our outpatient department a few weeks ago. The child had no congestive heart failure (CHF), was sleeping comfortably but had a heart rate of 130–140 bpm. Why should there be tachycardia in the absence of heart failure? Tachycardia is a response to CHF and not left ventricular (LV) dysfunction. Even so, the ECG of this child (this was the first ECG ever done since his illness!) showed normal PQRST relations (**Fig. 1**). A 24 hours Holter monitoring showed his heart rate was stuck at 130–140 bpm throughout day and night with very little circadian variation. An automatic atrial tachycardia was suspected, electrophysiological study done and an ectopic focus ablated. Heart rate came down to 80 bpm at rest and over 4–6 months, left ventricular function normalized.

Case Vignette 2

We have at least four families presenting in the last 6 months with multiple sudden infant death syndrome (SIDS) or a history of earlier children dying suddenly. At least one of them clearly has a LQTS identified (**Fig. 2**) when the child was put on a treadmill after repeated ECGs/Holter recordings had failed to show any abnormality. Even an epinephrine challenge had failed to identify a cause.

TACHYARRHYTHMIAS

A tachyarrhythmia is broadly defined as resting heart rates that are beyond the range of normal heart rate for the age of the child (**Table 1**).

GENESIS OF TACHYARRHYTHMIAS

The three basic mechanisms of tachyarrhythmias (re-entry, enhanced automaticity, and triggered activity) are outlined in **Table 2**.

Re-entrant Tachycardias

Re-entry or circus movement implies an impulse continuously going around a barrier. This occurs when an impulse proceeds in a differential manner along a pathway, either as a consequence of an anatomical barrier (e.g., scar) or a functional barrier (different electrophysiological properties). The following features essentially define a re-entrant circuit: (1) two distinct areas/pathways with different electrophysiological properties separated by (2) a *non-conducting, anatomic/functional barrier or area*, (3) unidirectional block, (4) a final common pathway, and (5) interruption of the re-entrant circuit at any point along its path should terminate the circus movement.

A typical example is an accessory pathway mediated tachycardia or a typical atrial flutter (AFL). The onset, offset and mechanism of an atrioventricular re-entrant tachycardias (AVRT) is shown in **Figures 3A to C**. The first beat shows a fused QRS wherein conduction through the pathway produces the delta wave but majority of QRS is inscribed rapidly through the His-Purkinje system (HPS). An atrial ectopic gets blocked in the accessory pathway (longer effective refractory period [ERP]) and renders it refractory for a short while. The impulse goes down the AV node-His bundle axis and reaches the accessory pathway from the ventricular end. This delay has allowed the pathway to recover its conduction and the impulse can now go retrograde into the atrium and reaches the AV node again, conduct orthodromically and sustains a *circus movement*. In case the delay has been insufficient for the AV node/His-bundle axis to have recovered conduction then the impulse gives only one extra P wave and no QRS and therefore no tachycardia. All re-entrant circuits therefore have to have a critical area of slow conduction that allows recovery of myocardial excitability to allow the circus movement to perpetuate.

Enhanced Automaticity

Several areas of the heart have had cells similar to the sinoatrial (SA) and AV nodes while in utero. In most cases these cells lose this ability of spontaneous automaticity as the fetus matures, thus leaving the SA node to be the dominant pacemaker. However, different reasons can make these areas fire again at a rate that is much more rapid than the normal rate. Such tachycardias arise from an ectopic location and do not obey the laws of re-entry. They may fire in short bursts lasting from a few seconds to hours or days. They are called incessant when they occupy more than 50% of the day. Atrial rates can be anywhere from 130/140 to more than 200/min. Typically, rates of 130–150 bpm are common, that may not cause symptoms. If this relatively fast rate persists for weeks to a few months it can lead to a reversible cardiomyopathy, called as *tachycardiomyopathy* (enumerated earlier). Atrial tachycardias (AT) form the most common example of enhanced automaticity and often present as TCMP in children.

Triggered Activity

This is the least common mechanism and is a term used to describe impulse initiation in cardiac fibers due to the occurrence of after-depolarizations (AD). These are oscillatory depolarizations that

Figure 1 Narrow QRS tachycardia in a 2-year-old at approximately 150 bpm. Notice the PR is short compared to the RP, implying this is a long RP tachycardia. A casual look shows a normal PQRS, suggesting this is sinus tachycardia. However, the child was sitting comfortably and had no congestive heart failure (CHF). A closer look shows negative P in aVR, a small positive P in inferior leads and a deep completely negative P in V1 (arrows). In general, inferior leads should show a good upright P wave during sinus tachycardia. V1 should normally be a + or a \pm deflection as the sinus node is a posterior structure and the current comes towards V1. These clues along with the fixed rate point towards an automatic atrial tachycardia

Figure 2 Twelve lead ECG taken during recovery phase of an exercise test. Blue arrows point to the beginning of QRS and green arrow at the end of T wave in Lead II. In Lead II, absolute QT is approximately 400 ms and RR is approximately 600 ms. QTc as per Bazett's formula comes to approximately 510 ms. Note the T wave notching (? U waves) in precordial leads V1-V4. If one labels them as U waves, the measurement should then be of the QTU interval. The QTU in V4 is 440 ms (purple arrow) which at an RR of 600 ms gives a QTc of 560 ms. QT interval can be different in between leads. While measuring ECG intervals like QT it is a good idea to keep either the beginning of Q or the end of the T on one of the thick lines of the ECG

follow the cardiac action potential. Two subclasses are traditionally recognized: (1) early (EAD), e.g., due to sotalol; and (2) delayed (DAD), e.g., digitalis toxicity and catecholaminergic polymorphic ventricular tachycardia (CPVT).

ETIOLOGY

Arrhythmias occur because of a large variety of reasons but most often the underlying heart is structurally normal. However,

abnormal hearts with depressed systemic ventricular function are also highly prone to get arrhythmias.

Structurally Normal Heart

- Most supraventricular tachycardias (SVTs) like AVRT, AV nodal re-entrant tachycardia (AVNRT) and ectopic atrial tachycardias (EAT) occur in a structurally normal heart.
- Some ventricular tachycardias (VTs) occur in structurally normal hearts. Common examples include those arising from

Table 1 Normal resting and exercise heart rates (beats per minute) for various ages

Age	Resting (sleeping)	Resting (awake)	Crying/exertion
Newborn	80–160	100–180	Up to 220
1 week to 3 months	80–200	100–220	Up to 220
3 months to 2 years	70–120	80–170	Up to 200
2–10 years	60–90	70–110	Up to 200
10 years to adult	50–90	55–90	Up to 200

Table 2 Basic mechanisms of arrhythmias and their common examples

- Re-entrant
 - AV re-entrant tachycardias (AVRT)
 - WPW, Concealed bypass tract, PJRT, Mahaim fibers
 - AV nodal re-entrant tachycardia (AVNRT)
 - Atrial flutter and intra-atrial re-entrant tachycardia (IART)
 - Atrial fibrillation
 - Scar related ventricular tachycardias
 - Fascicular VT, Torsades-de-pointes
- Enhanced automaticity

the fascicles of the left ventricle (fascicular tachycardia) and due to channelopathies like LQTS, Brugada syndrome, CPVT, etc.

- Metabolic and electrolyte derangements such as hyperkalemia, hypokalemia, hypothermia, hypoxia.
- Drugs like digoxin, adrenergic agonists, antiarrhythmics (most antiarrhythmic drugs are capable of causing new arrhythmias). Drugs like sotalol, terfenadine (an obsolete antihistaminic) that cause QT prolongation can precipitate torsades—these arrhythmias are labeled as *proarrhythmias*.
- Increased intracranial pressure.

Structural Heart Disease

- Primary atrial tachycardia (AT), atrial flutter (AFL), junctional ectopic tachycardia (JET) and VT may sometimes occur in acute postoperative settings.
- AFL and atrial fibrillation (AF) occur largely in the presence of structural heart disease. While AF typically occurs due to a large left atrium in rheumatic mitral valve disease, flutter can be seen in patients of atrial septal defects or postincisional surgical scars.
- Cardiomyopathies may also be associated with atrial and ventricular arrhythmias leading to VTs and sudden death.
- Cardiac tumors like rhabdomyoma, fibromas often lead to VT.

CLINICAL PRESENTATION AND DIAGNOSIS

Symptoms

These depend on the age of the child, underlying structural heart disease if any, duration of the tachycardia and parental education/awareness about the disease. Neonates and infants may present with tachypnea, poor feeding, vomiting, excessive crying or restlessness or excessive somnolence. Older children may complain of palpitations, chest pain, syncope or sometimes are unable to describe the peculiar feeling. Severe forms of arrhythmia can produce cardiovascular collapse, CHF, SCD and SIDS. Persistent SVT/VT can produce a DCM-like picture.

Figures 3A to C Tachycardia mechanism: re-entry (a: AV node, b: His-bundle, c: Right bundle, d: Left anterior fascicle, e: Left posterior fascicle, f: Left lateral accessory pathway (AP), g: SA Node). (A) Figure shows impulse originating from SA node (green arrows) and going to the ventricle through the His-Purkinje System (HPS) and the accessory pathway lying at the lateral mitral annulus (red, f). The ECG beat under it shows a short PR and the delta (δ) wave formed by the myocardial depolarization of the local muscle at the site of the accessory pathway insertion. For clarity we have shown the delta (δ) wave prominently—however, in general left lateral pathways do not have such a prominent delta (δ) wave as by the time the impulse reaches the pathway most of the ventricle has already got depolarized through the HPS; (B) Figure shows an atrial ectopic coming from the LA that gets blocked in the pathway but conducts through the HPS. Thus, there is no delta (δ) wave in the ECG. The beat comes back to the AP but finds the pathway still refractory and thus cannot get to the A again—hence there is no tachycardia; (C) Figure shows the same thing as in B, the only difference being that the AP has recovered. The beat goes back into the atrium (the negative P shows retrograde conduction) and reaches the AV node again. If the AV node has recovered by this time, it starts a tachycardia

Clinical Examination

If the physician is lucky, he may see the child during the arrhythmia, and note the abnormal heart rate and rhythm. A scar suggestive of previous surgery may suggest underlying heart disease. A careful examination of the precordium, neck vessels and hepatomegaly will point towards heart failure as a cause or effect of tachyarrhythmia. Observing the neck even in an infant is very useful to detect an ongoing tachycardia. The precordium may be hyperdynamic. Often the examination will be normal as there is no underlying structural heart disease.

SVTs are generally benign except for the symptoms that they produce. Orthodromic SVT in infants and children can occasionally be very rapid (ventricular rates of 250–300/min) and may lead to syncope and death. Most SVTs are *short RP*, implying PR interval will be very long thus making the atrium contract at an inappropriate time, often in ventricular systole against a closed AV valve. This, along with the rapid rate that leads to decreased cardiac output and stimulation of renin-angiotensin system leads to CHF sometimes within 3–4 hours of onset of tachycardia. Infants are typically more susceptible to go into CHF that is not due to ventricular *systolic* dysfunction and should not be labeled as TCMP (see earlier discussion). This CHF resolves within minutes of tachycardia termination and does not prevent use of β -blockers.

DIAGNOSIS OF ARRHYTHMIA

Even in the absence of the tachyarrhythmia, the ECG may point towards a specific disorder (e.g., Ebstein anomaly, Brugada syndrome, LQTS, short QT syndrome, digitalis toxicity, hypokalemia). Though QRS width is dependent on age, broadly a

QRS more than 120 ms is a wide QRS tachycardia. In general, SVTs are narrow QRS and VTs are broad QRS. However, a fascicular VT can be narrow and an antidromic tachycardia through an accessory pathway can be wide. Rate related aberrancy is uncommon in children and aberrancy if seen is due to pre-existing bundle branch block as in patients operated for tetralogy of Fallot (TOF). A standard dictum for a wide QRS tachycardia is not to use calcium channel blockers.

If a child is seen in a clinic/hospital in tachycardia every effort should be made to do a 12 channel ECG with simultaneous acquisition of all leads in a 12 \times 1 format (**Fig. 4**). Further, a continuous ECG should be recorded while doing any maneuver or injecting adenosine. Adenosine gives a very unpleasant feeling and most children move at that time, spoiling the ECG trace. We often give a sedative before giving adenosine so that a good record can be obtained. These recordings are very valuable as they help in making a diagnosis and long-term management. Ensure these recordings are either photocopied or digitized as thermal printouts can fade overtime. Recording at the rate 50 mm/s speed is of no use in identifying the tachycardia as the P waves get stretched and become indistinguishable from T or U waves. It may sometimes be useful when the tachycardia is extremely rapid, more than 260–270 bpm. A 50 paper speed is predominantly useful when one has to serially monitor QRS or QT duration over long-term.

Holter Monitoring

Continuous ambulatory 24–72 hours ECG recording can be used to pick-up episodes of tachycardia and to determine a symptom correlation. Obviously, infrequent episodes will not be picked up by such a short recording. More often a Holter can be useful

Figure 4 Importance of the 12 \times 1 stacked format ECG in arrhythmia diagnosis. Broad QRS tachycardia in a 12-year-old child. A line has been drawn on the QRS onset based on leads V1–V3 where it is best seen. Top arrow points to lead I QRS onset—seen in isolation it would have been impossible to say where QRS started. Bottom arrow on lead aVF, pasted onto a QRS away from the line for clarity. Notice the small positive wave just after T. This is not the P wave but is part of the QRS—on a single channel this would have been taken as P wave leading to an incorrect diagnosis. This is a broad QRS tachycardia with left axis and left bundle branch block (LBBB) morphology—differential diagnosis of such a tachycardia is— (a) Monomorphic ventricular tachycardia (VT) coming from the RV inflow, classical of arrhythmogenic right ventricular cardiomyopathy (ARVC), (b) Bundle branch re-entrant VT, an uncommon arrhythmia in children, (c) antidromic tachycardia through a Mahaim pathway, (d) orthodromic supraventricular tachycardia (SVT) with LBBB aberrancy

in diagnosing an automatic tachycardia (as in TCMP), pick-up intermittent pre-excitation, record ambient ventricular ectopy in the presence of structural heart disease especially post-TOF repair. Another setting wherein they may be useful is when looking for channelopathies like LQTS wherein the QT prolongation is often not present all the time. Systemic ventricular dysfunction or post-TOF repair children often get frequent ventricular ectopics as isolated beats, couplets, bigeminy, triplets, etc.—such patients maybe at a higher risk of SCD and may need more detailed evaluation. Too often we have seen Holters being prescribed for palpitations occurring once in a few months or even as a preoperative screening tool—Holter monitoring in children is not easy and is expensive too.

Cardiac Event Recorders/Mobile Cardiac Telemetry

These recorders in general are capable of recordings up to 1–2 weeks, generally of a single or at best two channels. They are useful if symptoms are occurring once in 1–2 weeks. With mobile technology integrating with ECG, devices are available which can be kept at home with the patient or worn 24/7. These devices will record a single channel on command and transmit through Bluetooth or similar technology to a mobile and then a remotely stationed server. We expect this technology and its variants will revolutionize arrhythmia detection, monitoring and management with remotely stationed experts giving real time feedback.

Exercise Testing

Exercise testing perhaps should be routinely done in evaluation of syncope, family history of sudden cardiac death or symptoms related to exercise. It may help in risk stratification of Wolff-Parkinson-White (WPW) syndrome and is useful in assessing adequacy of β -blockade and drugs like flecainide that show use dependence. LQTS, CPVT, arrhythmogenic right ventricular cardiomyopathy (ARVC) are typical settings wherein exercise test can help in the diagnosis (see earlier, **Fig. 2**). We have been able to make even 5–6 year-old do a short exercise ECG when needed.

Intracardiac Electrophysiological Studies

Intracardiac (or transesophageal in children) electrophysiological studies (EPS) have been available for a fairly long time and are supposed to be the most definitive tool in arrhythmia management. EPS has no role in evaluating bradycardias, be it Sick sinus syndrome or a 2:1 AV block. It is occasionally needed for risk stratification of WPW syndrome in children. In general, these studies are now done as a part of treatment wherein catheter ablation is performed simultaneously. Diagnostic EPS has a very limited role in the current era. VT induction is sometimes attempted in postoperative TOF patients to identify patients at high-risk of SCD. In adults, VT induction by EPS has been a debatable topic since over 30 years and will probably remain so till more reliable tools are invented.

SPECIFIC ARRHYTHMIAS AND THEIR MANAGEMENT

Common supraventricular arrhythmias are listed in **Table 3**.

Sinus Tachycardia (ST)

Sinus tachycardia is the most common dysrhythmia seen in practice—mostly it should not be called a dysrhythmia as it is physiological and appropriate for the need. There are two reasons for highlighting ST—(1) it is the single most important confounder in diagnosing an arrhythmia and (2) occasionally, the sinus node may fire at a higher rate than what is expected. When ST is not associated with a disease or an identifiable cause

Table 3 Supraventricular tachyarrhythmias

• AV Re-entrant tachycardia (73.2%) – Concealed bypass, WPW, PJRT, Mahaim fibers
• AV nodal re-entrant (12.5%)
• Primary atrial tachycardia (14.3%) – Atrial flutter and IART – Ectopic atrial tachycardia – Chaotic atrial rhythm – Atrial fibrillation
• Junctional ectopic tachycardia – Congenital – Postoperative

Abbreviations: WPW, Wolff-Parkinson-White (WPW) syndrome; PJRT, permanent junctional reciprocating tachycardia; IART, intra-atrial re-entrant tachycardia.

and the underlying heart is normal, it is labeled as *inappropriate sinus tachycardia*. This condition is difficult to recognize, diagnose and manage. Sinus tachycardia is a normal response to situations like exertion, fever and anxiety or more pathological states like hypotension, thyrotoxicosis, anemia, congestive heart failure and drugs like atropine and catecholamines. The treatment lies in the diagnosis and management of the underlying etiology. Following points are useful to differentiate sinus tachycardia from SVT:

- P waves with a morphology suggesting an abnormal origin—sinus P waves in lead aVR (in a solitus heart) should always be negative and should be positive in inferior leads
- Gradual onset and offset of tachycardia
- Presence of sinus arrhythmia (heart rate changes associated with breathing), though this maybe blunted
- PR prolongation during tachycardia goes against sinus tachycardia as sympathetic stimulation causing the ST should improve AV conduction and shorten it
- *Adenosine challenge* Sinus tachycardia rarely shows an AV block with an intravenous adenosine bolus while atrial tachycardia's generally show a transient AV block. The slowing/transient block also allows evaluation of P wave morphology as discussed earlier. Very sick children with borderline hemodynamics should not be given adenosine challenge as it leads to transient cardiac ischemia that can tilt the balance unfavorably.

Atrial Flutter

It is a re-entrant tachycardia usually confined to the right atrium wherein the circuit goes around the tricuspid annulus. It rarely occurs in the presence of normal heart, except in neonates and the elderly.

Neonatal atrial flutter is an intriguing entity. Most often, underlying structure and function is normal. The usual AFL is cavotricuspid isthmus (CTI) dependent which is the critical slow conducting zone (**Fig. 5**). Since it is a re-entrant arrhythmia one cannot pin point a location of origin. Earlier on a *typical flutter* was defined as one circulating in a counterclockwise direction around the tricuspid annulus in the frontal plane and *atypical* if it was in a clockwise direction. After recognizing that both these forms were essentially the same circuit and could be treated by ablating the isthmus, this terminology has become ambiguous. Most electrophysiologists call both these flutters as typical and flutters that do not use the CTI as atypical. Such atypical non-CTI dependent flutters are often seen to be going around postsurgical scars or in diseased atria. ECG in typical AFL shows the following:

- Dot regular and absolutely identical flutter waves (saw-tooth like P waves)

Figure 5 Three-channel ECG showing atrial flutter in a 3-day-old child. Note the typical saw tooth pattern which is more evident when the AV block increases to 3:1. There is no isoelectric baseline as the re-entrant circuit goes around the tricuspid annulus and there is no time in the cardiac cycle when the atria are electrically silent. In neonates, flutter may conduct 1:1 leading to a ventricular rate of around 300/min. This may obscure the saw tooth pattern and it may be difficult to diagnose flutter. IV Adenosine can be used to create a transient AV block which reveals the flutter waves. Flutter is a macro re-entrant tachycardia going around the tricuspid annulus in the right atrium

- Flutter wave rates are 250–350/min, often 300 bpm
- A fixed AV block (2:1 or 4:1) leads to a slower ventricular rate, typically 150/min
- A distinctive feature is the absence of an isoelectric baseline between the P waves.

A ventricular rate of 150/min with the P wave falling right in the middle of the 2 QRS complexes should arouse suspicion of a typical atrial flutter (rule of Bix).

Treatment

Atrial flutter is not easily amenable to drug therapy and therefore transesophageal pacing or DC cardioversion (DCCV) may be necessary. This is often the case in neonates in view of their hemodynamic instability, wherein once terminated it usually does not recur. Peculiarly, digoxin has been shown to be useful in preventing recurrences. Radiofrequency ablation in CTI dependent flutters has a high rate of success (90–100%) and may sometimes be needed if all drugs fail in preventing recurrences or terminating it.

Atrial Fibrillation

Characterized by an extremely fast atrial rate (350–600 per minute) with an irregularly irregular ventricular response, AF almost always occurs in the presence of structural heart disease with chronic rheumatic mitral valve disease being the most common cause in India. AF is uncommon in children and is important only in older children with WPW syndrome wherein it can lead to a rapid ventricular response through the accessory pathway and cause SCD. This may also happen if intravenous (IV) calcium channel blocker (CCB)/digoxin and sometimes even adenosine are given for an older child with WPW syndrome. It is mandatory to have a defibrillator ready when one gives IV adenosine for terminating SVTs in children with WPW syndrome. Since this may not be known in the first episode it is good practice to do this routinely.

Chaotic Atrial Rhythm

Also called as multifocal atrial tachycardia, chaotic atrial rhythm (CAR) is seen in early infancy (mostly < 3 years of age). It generally has a benign course and may be seen in children with dilated cardiomyopathy. ECG shows (1) multiple (at least three) distinct P-wave morphologies; (2) irregular P-P intervals; (3) isoelectric baseline between P-waves; and (4) ventricular rate more than

100 beats/min. It is a difficult tachycardia to treat and should best be dealt by an arrhythmia expert. One can try AV nodal blocking drugs to slow down the ventricular rate or Class Ic/III drugs.

SUPRAVENTRICULAR TACHYCARDIAS

These tachycardias were labeled earlier as junctional tachycardias as no P waves were seen during the tachycardia and therefore they were thought to be coming from the junction. Electrophysiological studies showed that P waves were generally hidden in the QRST segments; these tachycardias were thus labeled as *supraventricular tachycardias*.

There are three tachycardias that generally constitute this group: (1) AV nodal re-entrant tachycardia, (2) AV re-entrant tachycardia, and (3) automatic atrial tachycardia. The term *supraventricular tachycardia* is now used to encompass these tachycardias even though AVRT cannot occur without ventricular involvement. These tachycardias are in general narrow QRS and can be terminated by either drugs acting on the atrium or on the AV node. All tachycardias that arise from the ventricle are always (except for fascicular VT) broad QRS and are labeled as *monomorphic* or *polymorphic* ventricular tachycardia depending upon the ECG morphology of the tachycardia beats. Most SVTs, especially the re-entrant variety are not regular and in children show equal atrial and ventricular rates due to a *brisk* AV node.

Atrioventricular Re-entrant Tachycardia (Re-entrant Tachycardia over Accessory Pathway, Wolff-Parkinson-White Syndrome)

Accessory pathways are muscle fibers that connect the atrium or AV node to the ventricle outside the normal AV nodal-His-Purkinje conduction system (AVN-HPS). Conduction over accessory pathways may be anterograde (from atrium to ventricle) or retrograde (from ventricle to atrium). Anterograde conduction results in ventricular depolarization outside the His-Purkinje conduction system. Since ventricular conduction is slow, it inscribes a low frequency signal that results in a slow up stroke (slur) known as a *delta wave*. This pathway is thus *manifest* (**Fig. 6**). A pathway that only conducts from ventricles to atria (retrograde) will not manifest itself as a delta wave/pre-excitation and is thus known as *concealed*.

Figure 6 Wolff-Parkinson-White (WPW) syndrome in a child with recurrent episodes of supraventricular tachycardia (SVT). Note the delta waves in inferior leads. It is not normal to have a negative QRS in inferior leads. The P waves are relatively small (blue arrows) and so the short PR is not seen in all leads. The delta waves (red arrows) are negative in inferior leads, positive in I, V2. Based on this we found a pathway in the os of the coronary sinus where it was ablated using low powers. However, pre-excitation recurred after a few days, though the child has not had tachycardia again. Given the increase in incidence of atrial fibrillation with age, one may still have to ablate the pathway if its effective refractory period (ERP) is short, as it can lead to VF

The term *Wolff-Parkinson-White syndrome* is used when a manifest pathway leads to ECG changes and symptomatic tachycardia. An accessory pathway that does not give rise to symptoms or tachycardia is labeled as asymptomatic pre-excitation and not asymptomatic WPW. More recently it has been found that a manifest right sided pathway leads to dyssynchronous activation of the ventricles that can lead to severe left ventricular dysfunction similar to what happens in left bundle branch block. This DCM can be completely reversed by ablating the pathway and is different from TCMF.

Tachycardia in the presence of a pathway is mostly orthodromic, implying an atrial ectopic finds the accessory pathway refractory and travels down the HPS. Since this beat did not go to the ventricle through the pathway, there will be no delta wave on the ECG. The wave front exits into the ventricle through the HPS and proceeds retrogradely towards the base of the heart where it finds the accessory pathway no longer refractory and thus lets the impulse into the atrium. If the adjoining atrium and AVN-HPS have recovered the beat will go down into the ventricle and setup the tachycardia. The same can happen when a ventricular ectopic finds the HPS refractory and goes to the atrium through the pathway and lead to a circus movement. Uncommonly, the pathway may be having a shorter refractory period than the AVN-HPS and in this case the atrial ectopic goes down the pathway and comes up the AVN-HPS leading to an antidromic tachycardia. This tachycardia is a broad QRS one as the myocardium gets depolarized muscle to muscle starting eccentrically at the site of pathway insertion into the ventricle. This is exactly how a VT would behave if it was to start from the same muscle area—thus an antidromic tachycardia looks more like a VT on the ECG and behaves like one too. The long conduction time in the ventricle along with dyssynchronous activation often leads to hypotension and the treatment should be DCCV at the earliest. Adenosine may terminate the tachycardia by

blocking its retrograde conduction through the AV node.

Electrocardiographic Recognition, Orthodromic AVRT (Fig. 7)

- Narrow QRS, dot regular tachycardia with a rapid initial upstroke/downstroke
- Retrograde P wave occurs after QRS complex, in the ST segment, or early in the T wave occasionally causing ST segment depression or notching
- Presence of AV or VA block/dissociation rules out bypass mediated tachycardia
- QRS alternans and ST depression may be seen in same patients.

Electrocardiographic Recognition, Antidromic AVRT

- PR interval less than 120 ms during sinus rhythm. P waves are difficult to recognize as the QRS rate is often 250 and above, and the QRS is extremely broad
- QRS complexes are broad with a slow rise like a delta for the entire upstroke
- QRS complex duration exceeding 120 ms
- Secondary ST-T wave changes, directed opposite in direction to the major delta and QRS
- Regular QRS tachycardia, matching the pre-excited sinus rhythm ECG to an extent.

Not all pathways behave in the same fashion. Mahaim pathways are fibers that connect the atrium to the right bundle and lead to a wide QRS tachycardia of left bundle branch block (LBBB) morphology. The tachycardia has a LBBB morphology because conduction from right atrium goes directly into distal right bundle which activates the RV first and then LV. These pathways do not conduct retrogradely and are decremental in nature. The Lown-Ganong-Levine (LGL) syndrome comprises of tachycardia in the

Figure 7 Orthodromic AVRT at rate of approximately 235/min in a patient with Ebsteins anomaly and a huge right atrium. Note the arrows in lead II point to a sharp deflection after QRS-T waves are generally not this sharp. Note in V3, there is a very large P wave after the QRS. This is because of the large RA in an Ebsteins patient. This is a short RP tachycardia as the PR interval is more than 50% of the RR interval

presence of a short PR with a normal QRS and was believed to be due to fibers that either completely or partially bypass the AV node. These fibers do not insert into the ventricle or fascicle and hence do not lead to a delta wave. No specific tachycardia has been linked to these fibers and hence this entity is no longer considered clinically important.

An important tachycardia in neonates is the permanent junctional reciprocating tachycardia (PJRT) that is often incessant and frequently associated with left ventricular dysfunction. PJRT occurs because of a concealed bypass tract mostly located in the right posteroseptal region that conducts decrementally. Hence, when the propagating wavefront reaches the pathway, instead of going into the atrium rapidly it goes slowly. This allows the atrium and the AV node enough time to recover and thus perpetuate the tachycardia, making it incessant. This tachycardia is a classical long RP tachycardia as the maximum delay is in conduction from ventricle to the atrium and thus RP becomes more than PR. Since the pathway mostly lies in the posteroseptal region the wave front breaks low into the atrium and gives negative P waves in inferior leads. Typically, the tachycardia keeps breaking and restarting and therefore drugs like adenosine or DCCV are of no use. Since there is significant ventricular dysfunction associated with the tachycardia it may not be possible to give β -blockers. In most cases, one ends up using IV amiodarone followed by oral therapy. The pathway may lose conduction spontaneously overtime and the tachycardia thus may go away with time. RF ablation may be needed in some cases when the tachycardia is refractory.

Atrioventricular Nodal Re-entrant Tachycardia

The human AV node is a complex structure with a compact part, two inferior extensions and multiple transitional components that channelize conduction. This leads to uneven conduction creating a *functional dual physiology* that typically increases with advancing age. Thus, there is a *fast* pathway that lies superiorly and shows faster conduction with a longer refractory period compared to the inferiorly lying *slow* pathway. This results in formation of a circus

movement involving parts of the AV node and atrium, causing different tachycardias that bear specific characteristics. This tachycardia called AVNRT can be typical or atypical depending on how the conduction proceeds along these *pathways*. The typical variety shows antegrade conduction down the slow pathway and retrograde conduction via the fast pathway. The His-bundle and ventricle are activated passively and are not part of the tachycardia circuit. This tachycardia is rarely seen in infants and increases in frequency with increasing age, outstripping AVRT as the dominant mechanism in adults. In children, it shows the following characteristics:

- Usually there is 1:1 AV conduction with ventricular rates more than 200–250 beats/min.
- The QRS complex is normal in contour and duration, unless functional aberrant ventricular conduction or a previous conduction defect exists, which is uncommon in children.
- P waves are generally buried in the QRS complex. Often, the P wave occurs just after the end of the QRS and causes a subtle alteration in the terminal QRS complex that results in a pseudo-S or pseudo-r', which may be recognized only on comparison with the QRS complex in normal sinus rhythm (**Fig. 8**).
- AV nodal re-entry begins abruptly, usually after a premature atrial contraction (PAC) that conducts with a prolonged PR interval.

Ectopic/Automatic Atrial Tachycardia

Atrial tachycardia is the second most important cause of a regular SVT in children—in older children and adults its incidence is much lower than AVNRT. Most atrial tachycardias are due to enhanced automaticity wherein some part of the *atria* starts firing abruptly. More recently it has been found that even the venous structures like pulmonary veins, superior vena cava (SVC) and coronary sinus can lead to an automatic tachycardia. In general, such automatic tachycardias occur from specific locations, probably those which in utero had *sinus node* like cells that failed to involute completely.

Figure 8 Narrow QRS supraventricular tachycardia (SVT) at 200/min. No P waves are seen—the retrograde P waves occur so early that they get buried within the QRS. Since the retrograde breakthrough occurs from the AV node which is a relatively posterior/inferior structure in the atria, P waves are negative in inferior leads appearing as pseudo-S waves. Note the Pseudo-r' waves in lead V1 (arrows) that are also P waves

Secondary causes like myocarditis, elevated atrial pressures and atrial stretch can also trigger some areas to fire rapidly.

Given that AF is very uncommon in children it may be of interest to pediatricians that the common garden nonvalvar AF actually starts from a pulmonary vein muscle sleeve that starts discharging very rapidly. This very high rate gradually leads to atrial dilatation and structural changes which then perpetuates AF. This is why *pulmonary vein isolation* is now first-line treatment for AF. Given that atrial tachycardias are nonre-entrant, the ECG and its management is quite different from the other SVTs. Depending on the site of the focus causing tachycardia following features are observed:

- The tachycardia is often a long RP tachycardia. This is because PR interval remains normal or may increase marginally if the rate is very high. However, short RP intervals do not rule out an EAT.
- Usually has an abnormal P-wave axis (e.g., inverted in the inferior leads II, III and aVF when the focus is lying in the low atrium). P waves should be seen in Leads aVR, Inferior and V1 (see earlier discussion on sinus P waves), to determine whether they are sinus or not sinus. This may not be easy in a fast tachycardia wherein the P gets buried into the T.
- P wave morphology may be abnormal—it may be narrower or broader or more peaked.
- QRS complexes have a normal morphology unless there is a pre-existing bundle branch block, accessory pathway, or rate related aberrant conduction. It is possible to see a 2:1 AV response or even higher grade of block. Presence of any AV block during a narrow QRS SVT excludes AVRT.
- Isoelectric baseline is seen unlike AFL.
- Minimal diurnal variation in the rate—most often the atrial rate remains fixed at a single value or varies by a few milliseconds. Some EATs maybe more sympathetic dependent and show rate variation in the range of 30–40 bpm. A tachycardia that is disproportionate to the child's clinical condition is often an EAT.
- *Adenosine challenge*: May terminate nearly 30% of EATs. Otherwise shows several short periods of AV block with the A rate remaining unchanged. Here lies the importance of recording this on paper as the monitor may give an incorrect impression of the tachycardia stopping or restarting. This happens because the most evident wave on the monitor is the QRS which actually decrease because of the AV block.

Figure 9 provides ECG clues to identify the SVT mechanism.

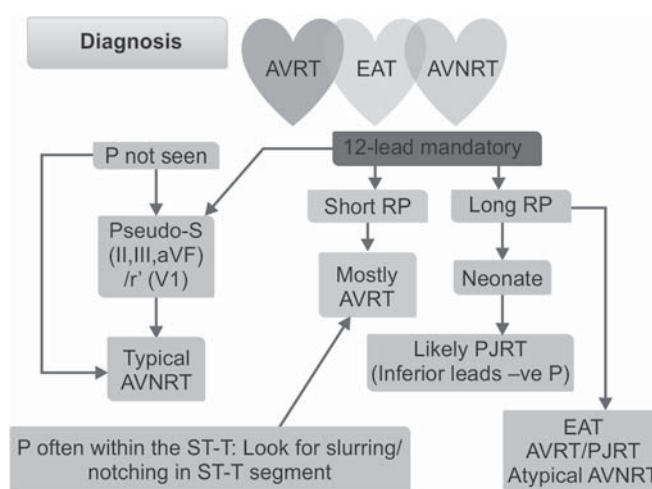

Figure 9 Paroxysmal supraventricular tachycardia (PSVT): ECG diagnosis algorithm. Every effort should be made to do a 12 lead ECG. In general these three tachycardias are dot regular, though AV block may occur with an EAT that could make the QRS irregular. The most important part of the diagnosis is to hunt out the P waves (see text). Once P waves have been identified it becomes fairly simple. Other clues that may help are: (1) Presence of AV block excludes AVRT, (2) QRS alternans favors AVRT, (3) ST, T depression favors AVRT
Abbreviations: AVRT, atrioventricular re-entrant tachycardia; PJRT, permanent junctional reciprocating tachycardia; EAT, ectopic atrial tachycardia; AVNRT, atrioventricular nodal re-entry tachycardia.

Acute Management of Supraventricular Tachycardia

The acute management depends on underlying structural heart disease, pre-excitation, age of the child, likely mechanism of tachycardia, hemodynamic status, especially heart failure due to a mechanical AV dyssynchrony and the fast rate itself. Left ventricular function cannot be assessed during the tachycardia because of the fast rate, incomplete filling of the ventricles an altered AV relationship and other factors. Based on the earlier factors and the child's blood pressure, peripheral signs of low cardiac output, etc., management options are chosen.

It is essential in today's era that a good quality simultaneously acquired 12-lead ECG in the 12 × 1 format is recorded prior to any treatment and also when the treatment is going on. Thus, if there

are facilities to record everything in a 12-lead format on the monitor itself that would suffice. If not, it is ideal to keep a 12-lead ECG running whenever an *intervention* is done. In a hemodynamically stable child, vagal maneuvers could be tried before pharmacologic therapy, though success rates are low and most of us in practical settings hardly ever use it.

Vagal Maneuvers

Traditionally include ocular pressure, Valsalva/pressure on infant's abdomen, carotid sinus massage, gagging and icebag application/Dive reflex. *Ocular pressure is contraindicated in infants and children less than 2 years and in general is no longer advocated for even adults.* The same applies for pressure on the abdomen especially if liver is enlarged, that is not uncommon in infants with a SVT lasting over 3–4 hours. Carotid sinus massage is acceptable in older children but has to be done correctly. Too often the pressure is either inadequate or improperly applied. It is important to apply pressure good enough to dent a tennis ball but not obliterate the pulse. Pressure should be applied towards the vertebral column, i.e., posteromedially and not more than 5 seconds at one time. It can be repeated on the other side or on the same side. Icebag application if done properly has been shown in some studies to have a 90% efficacy rate. A plastic bag of sufficient size to cover the entire face should be filled with one-third ice, one-third water and applied on the child's face for 10 seconds. It can be reapplied after a minute or so if the first application fails. The traditional method of immersing the child's face into cold water should not be attempted and applying a cold wet towel to the face is not effective. It is important that one wipes the face after the icebag application with a warm cloth to avoid cold panniculitis. The technique is rather cumbersome and not as successful as described by some. However, it has been seen that this in combination with adenosine (either simultaneous or immediate postapplication) maybe successful when the initial adenosine failed.

Adenosine

Intravenous adenosine is the treatment of choice for SVT because of its ultrashort duration of action and therefore a low incidence of complications. It has a 95% efficacy in re-entrant SVTs that is slightly higher than calcium channel blockers that are also effective in over 90% of cases.

Serious adverse effects occur occasionally and include: apnea/bronchospasm, accelerated and prolonged ventricular rhythm, prolonged asystole, proadrenergic effect enhancing AV conduction and shortening of the ERP of the accessory pathway leading to ventricular fibrillation (VF). It is important that the drug is pushed as a bolus and 5–10 mL of saline pushed in immediately after it. No blood should be allowed to come in contact with the drug outside the body as that metabolizes the drug instantly rendering it ineffective. Hence, new syringes and a new three-way need to be taken for every push. Although doses of 0.05 mg/kg may be effective and most texts generally recommend using 0.1 mg/kg and escalating up if tachycardia does not respond, we prefer to straightaway use a dose of 0.15–0.2 mg/kg, that is more predictable and saves on the cost and unpleasantness of repeated administration.

Intravenous Verapamil/Diltiazem

Intravenous verapamil/diltiazem has a more than 90% efficacy rate in terminating a routine re-entrant SVT, i.e., AVNRT and AVRT. The drug should be given slowly, unlike adenosine, as a rapid push can lead to unstable hemodynamics. It is contraindicated in infants (< 2 years of age), presence of CHF/prolonged tachycardia, manifest pre-excitation and previous β -blocker therapy. In older children, CCBs are effective and safe.

Overdrive Pacing

Pacing at a rate faster than the tachycardia from the atrium or ventricle is highly effective in terminating re-entrant tachycardias. Overdrive pacing can be done by placing a pacing catheter either in the esophagus or by the transvenous route in the atrium or the ventricle. It acts by rendering tissue ahead of the tachycardia refractory, thus stopping the circus movement responsible for the tachycardia.

DC Cardioversion

It is the treatment of choice for all hemodynamically unstable arrhythmias and for other SVTs not responding to all other techniques/medications. Cardioversion facilities should be available wherever medical termination is being attempted because of the rare occurrence of VF due to enhanced conduction over the accessory pathway.

Biphasic shock is now considered more efficacious and needs less energy for cardioversion. Most SVTs and AFL will respond to as low as 0.25–0.5 Joules/kg whereas VF may need up to 4 Joules/kg, which is the maximal dose permitted for a child. Most tachycardias will respond to DC version though automatic foci may be unresponsive in over 50–70% or recur immediately after converting.

Intravenous Amiodarone

It is useful in a wide variety of arrhythmias. The effect on the AV node usually occurs within 10–15 min, though the Class III effect usually takes 10–12 hours. When given IV the predominant immediate action is β - and Ca channel blockade that successfully reverts most re-entrant tachycardias using the AV node. The IV bolus dose has to be followed by a continuous infusion to maintain the effect. Amiodarone is effective in most automatic tachycardias like EAT, JET and some VTs. IV amiodarone is not innocuous and the threshold for starting it ought to be high; there is a in general serious over-tendency towards using amiodarone as most people believe it is very safe *acutely*. Acute side effects include severe hypotension and cardiogenic shock, acute fulminant liver failure leading to death, acute chest infiltrates needing oxygen and medication, etc.

Figure 10 provides an algorithm for acute management of a regular SVT.

Supraventricular Tachycardia: Chronic Prophylaxis

Once an acute SVT episode has been taken care of, the clinician needs to decide how to prevent future episodes. In general, medication need not be started after the first episode of an SVT unless the SVT was life-threatening or needed DCCV or the child lives in a remote area and cannot reach a hospital in less than 5–6 hours.

When to Start Prophylactic Therapy?

Most SVTs are hemodynamically stable—hemodynamic stability does not mean a normal blood pressure only. One has to see the complete picture implying look for signs of low cardiac output, CHF, labored respiration, a very high ventricular rate etc. Instability generally happens if underlying heart is abnormal, the ventricular rate is too high reaching 270–300 bpm, child was already on β -blockers and someone gave IV CCB, the tachycardia is antidromic and other causes.

Typically, our approach is not to start long-term medication unless there is an ECG documented SVT and the child has had more than one definite sustained episode. Even so, asking a child to take 1 or 2 pills everyday to prevent a self-terminating, hemodynamically stable episode occurring once in 6–12 months may be an overkill. This is important as once drug therapy has

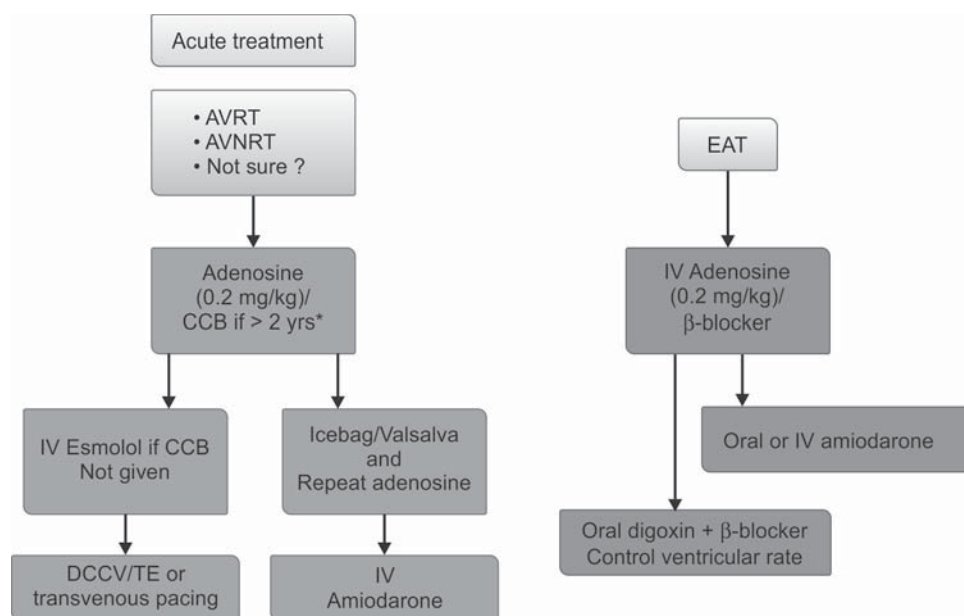

Figure 10 Management algorithm for an ongoing supraventricular tachycardia (SVT). If child is in shock or significant congestive heart failure (CHF), synchronized DC cardioversion (DCCV) with 1–4 J/kg should be done immediately. Re-entrant tachycardias will respond to DCCV but ectopic atrial tachycardia (EAT) would not. IV adenosine is the most favored drug though in older children IV verapamil or diltiazem are effective, safe and much cheaper

*Calcium channel blockers (CCBs) should not be used if child is hemodynamically unstable, < 2 years of age, taking oral β -blockers, known to have Wolff-Parkinson-White (WPW) syndrome or the tachycardia is a wide QRS one. Giving adenosine correctly is very important (see text). Icebag application is also an effective way especially if initial adenosine has failed for some reason

Abbreviations: AVRT, atrioventricular re-entrant tachycardia; EAT, ectopic atrial tachycardia; AVNRT, atrioventricular nodal re-entry tachycardia; TE, transesophageal pacing.

been started it will most likely continue for several years unless tachycardia resolves by itself or a catheter ablation is done. Losing pre-excitation is not at all uncommon in infancy and the same implies for an EAT. Even if pre-excitation persists the child may stop having an SVT as the accessory pathway (AP) may have stopped conducting retrogradely.

If tachycardia in an infant persists beyond 2–3 years it is unlikely to resolve. Uncommonly an AP that has stopped conducting in infancy, may come back at a later age. One needs to remember that AP is essentially a *congenital heart disease* implying it was present at birth—an AP cannot be acquired later in life. Even 70- or 80-year-old can be having an AP that remained undetected as it was concealed or an ECG was never done for the person. One other consideration before starting prophylactic drug therapy is to consider *pill in the pocket* approach that has been used successfully in adults with SVT and AF. It should be remembered that the first termination using this approach has to be done in a monitored hospital setting.

Which Drug to Start?

Once the decision for starting medication has been taken the doctor needs to decide what drug to start. In general, *digoxin*, β -blockers and CCBs are safe drugs with no proarrhythmic potential. The therapeutic range of digoxin is narrow and overdose, hypokalemia, and drug interactions need to be kept in mind and explained to the patient/parents. It is a common belief that children tolerate a higher dose of digoxin up to 10 $\mu\text{g}/\text{kg}$. This is true for children less than 4 years of age and when split into two doses. As far as possible one should not use doses more than 5 $\mu\text{g}/\text{kg}$. Digoxin can be safely combined either with β -blockers or with CCBs.

Medical literature is full of *blanket statements* like digoxin increase mortality when given as a prophylactic agent in WPW

syndrome as it shortens the refractory period of the AP and thus allows antidromic conduction that can take the ventricular rate beyond 300/min or induce VF. This can happen if the patient gets AF or starts conducting antidromically. AF is rare in children and there is no proof that digoxin increases the incidence of antidromic tachycardia *vis a vis* orthodromic tachycardia (generally 90% of SVTs in WPW are orthodromic). To us, the few reports that led to this conclusion of digoxin being harmful in WPW syndrome are not based on rigorous scrutiny. Even so, digoxin should not be first line for WPW syndrome and neither should it be CCBs. Even β -blockers that are in general first line therapy have been proclaimed harmful because it slows AV nodal conduction and hence would increase antidromic tachycardia. This again, is going beyond evidence, experience and *built on theoretical concerns*. We prefer to start with metoprolol in twice daily doses starting at 1 mg/kg/dose. This dose can be increased rapidly based on resting heart rates and blood pressure. If tachycardia recurrences continue despite *adequate* β -blockade one can add digoxin or flecainide/propafenone.

Class Ic drugs like flecainide and propafenone are highly effective drugs and safe when used in normal hearts and in the correct manner. Sotalol, a class III drug is also very useful but can lead to QT prolongation and polymorphic VT (TdP). These drugs should always be started in hospital under ECG monitoring and by physicians experienced in their use. It is important for pediatricians following up such patients to do ECGs regularly (once in 2–3 months) and monitor the QRS/QT intervals. QT prolongation beyond 520 ms, QRS prolongation more than 20–25% or appearance of any conduction defect are to be taken seriously and the drug either stopped or doses readjusted. Milk and milk products alter flecainide absorption and the child should not be given milk/milk products, 2 hours pre- or post-flecainide dose. Flecainide/propafenone should always be used with an AV nodal blocking drug.

Amiodarone should not be used in a routine SVT—neither acutely nor for chronic prophylaxis. We prefer to go for a catheter ablation rather than use amiodarone for more than 6–12 months in any child of any age.

Catheter ablation has revolutionized the management of arrhythmias and in adults it is now used even for arrhythmias like AF, VF, Torsades-de-Pointes, and ischemic VT. Radiofrequency ablation remains the preferred choice with cryoablation having some role in children wherein there is a risk of complete heart block when ablating. The Heart Rhythm Society (HRS) of the US had laid down guidelines for catheter ablation in children in 2002. These guidelines provide a framework that one can build upon. In our view the role of catheter ablation can be understood when one looks at the algorithms and **Table 4**. No cardiac intervention is a zero risk procedure and therefore the referring pediatrician has to be aware of those before deciding for it. **Table 5** summarizes

Table 4 Indications for catheter ablation in children

<i>Definite indications irrespective of age and/or weight</i>
<ul style="list-style-type: none"> Life-threatening tachycardia Tachycardia refractory to medical treatment defined as failed Class Ic and Class III <ul style="list-style-type: none"> Amiodarone may be used for 6 months to an year to tide over Tachycardia associated with significant left ventricular dysfunction High-risk WPW syndrome defined by aborted SCA or <ul style="list-style-type: none"> Recurrent syncope or single syncope plus high-risk markers Manifest pre-excitation associated with significant LV dysfunction Recurrent VT associated with hemodynamic compromise and amenable to catheter ablation Impending congenital heart surgery when vascular or chamber access may be restricted following surgery Parents unable to give medications properly or staying remotely and cannot access medical care quickly Tachycardia not responsive to adenosine/conventional antiarrhythmics and needs DCCV Persistent atrial flutter in a child > 4 years/15 kg
<i>Relative indications: age, weight may need to be factored</i>
<ul style="list-style-type: none"> Recurrent or symptomatic SVT refractory to conventional medical therapy in a child > 4 years/15 kg Adolescent child > 8–10 years with recurrent SVT not wanting to be on medication or getting side effects WPW syndrome in a child > 8–10 years with either high-risk pathway or inability to estimate risk noninvasively Asymptomatic pre-excitation—adolescent child with proven high-risk. Children < 4–5 years do not need to be tested Persistent atrial flutter in a child < 4 years/15 kg SVT with structural heart disease especially Ebsteins anomaly
<i>Notes</i>
<ul style="list-style-type: none"> Nonsustained arrhythmias in the absence of symptoms or ventricular dysfunction should not be taken for catheter ablation First episode of an SVT should not be offered ablation unless child had significant hemodynamic problems and/or was unresponsive to conventional measures Anesthesia often suppresses arrhythmias especially automatic tachycardias. Hence, such patients should be taken up only if they have incessant tachycardia or are big enough to be managed with minimal medications AVNRT, right midseptal and anteroseptal pathways, are close to the AV node. Ablation should be generally deferred till 12–15 years of age unless significant symptoms are present Conventional antiarrhythmic therapy implies digoxin, β-blockers, CCBs <p><i>The abovementioned indications are based on authors experience and not part of any standard guidelines.</i></p>

Abbreviations: SCA, sudden cardiac death; VT, ventricular tachycardia; LV, left ventricle; AVNRT, atrioventricular nodal re-entrant tachycardia; CCBs, calcium channel blockers; DC, direct current cardioversion; SVT, supraventricular tachycardia.

Table 5 Complications/potential harms of catheter ablation in children

<ul style="list-style-type: none"> Vascular access related <ul style="list-style-type: none"> DVT Hematoma, bleeding, local site infection Femoral arterial occlusion if an arterial access was taken and procedure was long, inadequate heparinization, large sheath Lesion related <ul style="list-style-type: none"> AV block, CHB: < 1%, predominantly in AVNRT, pathways close to AV node Acute/chronic coronary injury, phrenic nerve injury Tissue rupture/cardiac perforation at ablation site Pericardial effusion/tamponade Thromboembolism and stroke Increase in lesion size with growth—initial fears not proven Catheter related <ul style="list-style-type: none"> Injury/perforation of coronary sinus Valve damage
<ul style="list-style-type: none"> <i>Radiation related:</i> Depends on procedure time <i>Anesthesia related</i> if GA given <i>Death:</i> Very rare. Can be due to several causes.

Abbreviations: DVT, deep vein thrombosis; CHB, complete heart block; AVNRT, atrioventricular nodal re-entrant tachycardia; GA, general anesthesia.

some of the complications of catheter ablation. Having said that, if needed catheter ablation can be successfully done even in a 3 kg neonate with minimal risk, predominantly of venous thrombosis from where the access is taken. It would not be an overstatement if one says that in today's era no child should die due to a sustained tachyarrhythmia or WPW syndrome in the absence of structural/electrical heart disease. In India catheter ablation in children is currently being done by adult electrophysiologists. In an unpublished informal survey conducted by us around 2 years ago we found that less than twenty children weighing less than 15 kg had an ablation done in India in an year. We chose 15 kg as the cut-off as it has been found that complications are higher in them when compared to children weighing more than 15 kg. A major problem of doing small children is the unavailability of appropriate sized hardware, something pediatricians are well familiar with when they prescribe tablets that need to be given 1/8th or 1/10th. Cryoablation is still not available in India and therefore one has to try and avoid doing ablations close to the native conduction system that could result in a heart block. Electrophysiological tools are getting more and more sophisticated with 3 dimensional mapping systems like the CARTO (Biosense Ltd, Tirat-HaCarmel, Israel) and ENSITE (St Jude Medical Inc., St Paul, MN, US) providing real time signals superimposed on computed tomography (CT) images. These are very useful for ablating complex arrhythmias or reducing radiation.

Flow charts 1 to 4 illustrate algorithms for chronic management of supraventricular tachycardias.

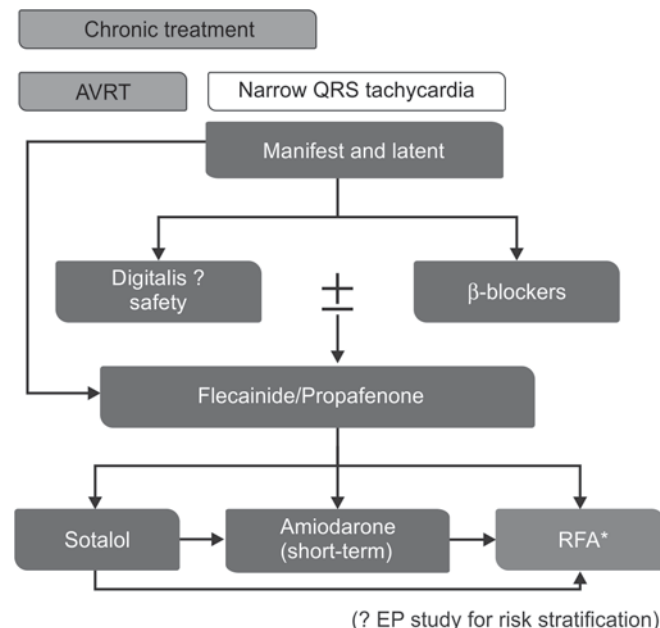

Junctional Ectopic Tachycardia

It usually occurs in a postoperative setting, with 5–10% children developing JET after surgery for congenital heart disease. Congenital JET in the absence of cardiac surgery is very uncommon. JET may be incessant in younger children and lead to TCMP. Presence of AV dissociation in a narrow QRS complex tachycardia is diagnostic of JET.

Treatment

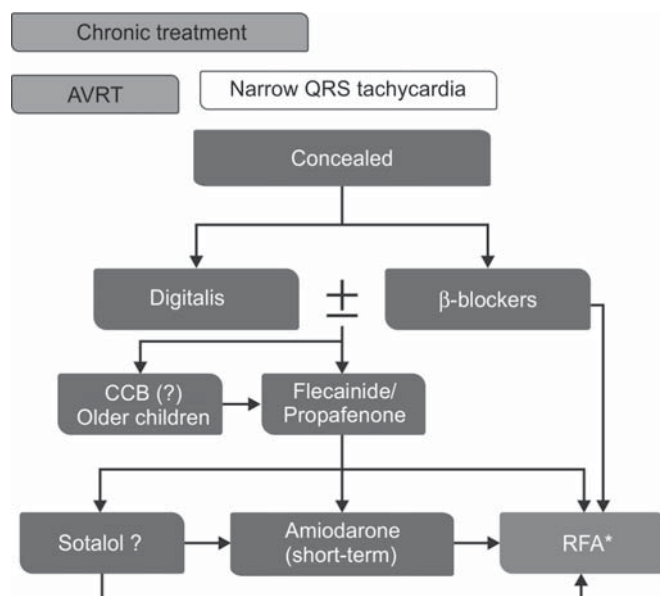

Intravenous infusion of cold saline in addition to surface cooling, to achieve a core temperature of 32–34°C—needs the child to be on a ventilator. IV vasopressors need to be minimized. AV synchrony can be achieved either by restoration of sinus rhythm

Flow chart 1 Drug treatment for preventing re-urrences in Wolff-Parkinson-White (WPW) syndrome. Latent pathways are pathways that have antegrade conduction that manifests only when some intervention is done. These pathways have the same risk as manifest pathways. Use of digitalis in manifest pathways is questionable (see text for discussion). Similarly use of sotalol for a benign arrhythmia like supraventricular tachycardia (SVT) may not be a good choice. Risk stratification by an electrophysiologic (EP) study is carried out by several groups in the US and RFA done for high-risk pathways even in young children

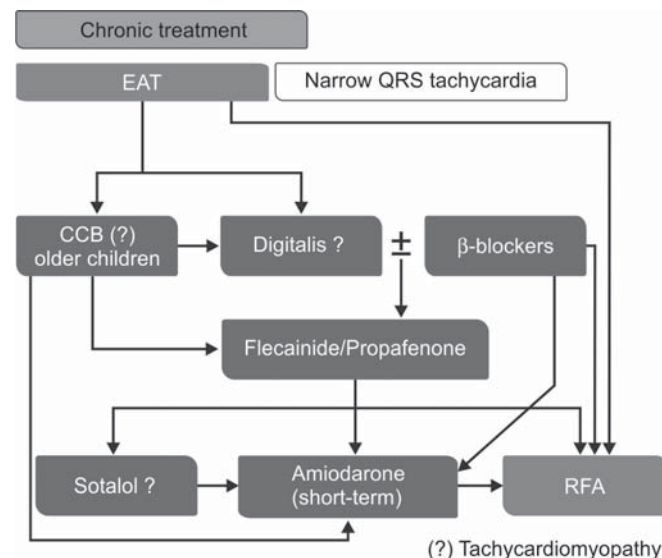

Abbreviation: AVRT, atrioventricular re-entrant tachycardia.

Flow chart 2 Algorithm for concealed APs. Since they do not have antegrade conduction the risk of sudden cardiac death (SCD) is much lower than Wolff-Parkinson-White (WPW) syndrome. Hence, both digitalis and calcium channel blockers (CCBs) can be used safely. In refractory supraventricular tachycardias (SVTs) combination therapies like flecainide with sotalol or amiodarone have been used by some. We feel RFA should be done rather than use relatively dangerous antiarrhythmics

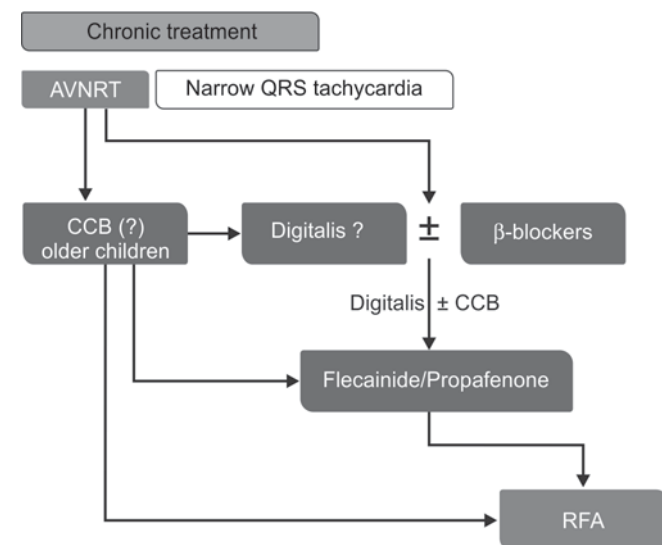

Abbreviation: AVRT, atrioventricular re-entrant tachycardia.

Flow chart 3 Therapy for ectopic atrial tachycardias can be started in the same way. However, most ectopic atrial tachycardias (EATs) do not terminate with this combination, but ventricular rate slowing maybe a reasonable endpoint. Amiodarone is a useful drug to restore sinus rhythm especially if there is severe left ventricular dysfunction which excludes use of Class Ic drugs. Presence of tachycardiomyopathy is an indication for early RFA or one could use amiodarone for a few months, let the LV function improve and then use safer drugs or ablate

Abbreviation: EAT, ectopic atrial tachycardia.

Flow chart 4 Atrioventricular nodal re-entry tachycardia (AVNRT) is an uncommon arrhythmia in small children. It can be easily managed by drugs like digoxin, β-blockers or calcium channel blockers (CCBs) or their combination. Radiofrequency (RF) ablation should not be attempted unless it is refractory or the child reaches adulthood. Risk of complete heart block is < 1 in 1,000 in experienced centers in adults. In children it may not be that low as the triangle of Koch is smaller. Cryoablation maybe preferable as it is safer than RFA

or atrial pacing. IV amiodarone in general reverts the tachycardia. Prior to reversion it may lead to a decrease in the rate and allow atrial capture with dual chamber pacing. It can be combined with flecainide in refractory JET. Oral amiodarone can be given to a child with stable hemodynamics and 2-3 days postprocedure.

Radiofrequency ablation has been attempted but has a high risk of complete heart block (CHB) and should be attempted only if tachycardia is life-threatening not responding to conventional means.

VENTRICULAR TACHYCARDIA AND VENTRICULAR FIBRILLATION

Ventricular tachycardia classically presents as a wide QRS tachycardia. QRS width is dependent on the age of the child and should be interpreted accordingly. In neonates a QRS width more than 80 ms is clearly abnormal. Widening of QRS may be very subtle and missed. The presence of AV dissociation in the presence of fast ventricular rate should suggest VT. It is important to note that Vs should be more than As as AV dissociation can be seen in complete heart block too.

Types

Monomorphic VT in the presence of a normal underlying heart can be stable and therefore hemodynamic instability should not be considered as evidence for VT. A sustained VT can result in hemodynamic compromise and VF. *Polymorphic VT* is generally rapid and leads to hemodynamic compromise. VT can be seen in very diverse circumstances. *Fascicular VT*, also called as idiopathic LVT can be seen with a normal heart. A similar VT morphology with a slightly wider QRS (complete LBBB) can also be using the fascicles in the presence of LV dysfunction, that is called as a *bundle branch re-entrant VT*.

Diseases like LQTS that were earlier called as primary electrical diseases of the heart are now grouped under the umbrella of *Channelopathies* as these occur due to abnormalities in the ion channels of the heart. Structurally these hearts are completely normal. Most of these diseases are inherited and are associated with sudden cardiac death. Genetic screening/testing has therefore become a very important tool in management of these diseases and SCD.

Etiology

The common causes of VT are as follows:

- Myocarditis, myocardial ischemia or infarction.
- Cardiomyopathies—dilated and hypertrophied types and in noncompaction of left ventricle.
- Cardiac tumors like rhabdomyomas, myocardial hamartomas (Purkinje cell tumors), fibromas and histiocytic tumors.
- Several congenital heart diseases are prone to develop ventricular arrhythmias either as such or due to the ventricular dysfunction they produce. Almost one-third of patients of Eisenmenger syndrome die suddenly, presumably due to a ventricular arrhythmia. Patients of TOF repair gradually develop RV enlargement due to the pulmonic regurgitation that most of them are left with. Such patients often develop VT that is re-entrant going around the VSD patch or using the RVOT.
- Channelopathies like LQTS, Brugada syndrome, catecholaminergic VT, short QT syndrome and others. Ion channel problems are also seen in arrhythmogenic right ventricular dysplasia (ARVD) in which RV myocardial thinning occurs with replacement by fibrous tissue and fat. This disease is also labeled as a cardiomyopathy as right ventricular dilatation and dysfunction are an integral part of it.
- Drug toxicity, e.g., digitalis, catecholamines, theophyllines, etc. Most antiarrhythmics are themselves proarrhythmic as they alter channel conduction.
- Idiopathic (fascicular VT) and right ventricular/left ventricular outflow VT—both occur on an underlying normal heart.
- Electrolyte disturbances like hypokalemia, hypocalcemia can also lead to VT.

Conditions Causing Ventricular Tachycardia/ Ventricular Fibrillation

Long QT Syndrome

QT prolongation can lead to a polymorphic VT called as Torsades-de-Pointes. QT may be prolonged either as a genetic defect or it may be *acquired* with common offenders being drugs, hypokalemia, hypocalcemia, intracranial hypertension, etc. Antiarrhythmics (quinidine, sotalol, amiodarone), antihistaminics like terfenadine, antibiotics like quinolones, motility agents like cisapride and several other drugs have been associated with QT prolongation with some of them being discontinued because of this.

The *congenital variety* is typically adrenergic dependent and has several subtypes based on the exact genetic defect and the channel affected. In LQT1, the most common variant of LQTS, patients typically get a VT during exercise while in LQT2 events are triggered by startle or auditory stimuli. LQT3 is one of the more malignant forms wherein events occur during sleep or inactivity. Diagnosis of LQTS is easy when the ECG shows the same or when a family member has already been diagnosed as having the problem. However, these patients may not show a long QT all the time and even 24 hours Holter recordings may fail to pick it up. Patients presenting with syncope or sudden cardiac arrest as the only manifestation may need intensive evaluation before one hits the diagnosis. An exercise test can be very useful in provoking the QT abnormality and should be part and parcel of evaluation of syncope. It is not uncommon to find LQT in patients being treated for refractory seizures. Diagnostic criteria for LQT exist but broadly an unequivocal diagnosis of LQT is made if it is more than 480 ms. Lesser degrees or prolongation will need supportive evidence. It is possible that patients getting torsades due to drugs actually have a subclinical genetic defect that gets provoked. Typically the drug induced torsades is pause dependent wherein an early coupled ectopic falls on the T wave that occurs late because of the preceding pause.

Management depends of the variant type. In general, high dose β -blockers in combination with atrial pacing form the mainstay of treatment. Left cardiac sympathetic denervation and implantable cardioverter defibrillator (ICD) implantation may be done in carefully selected patients. Management of a drug induced torsades in the emergency room maybe stabilized by isoprenaline infusion, pacing and IV magnesium. It may seem paradoxical that one uses isoprenaline and β -blockers for the same disease. Acutely if pauses are seen, isoprenaline is useful. β -blockers help in prophylaxis for recurrences.

Catecholaminergic Polymorphic Ventricular Tachycardia

This is characterized by a bidirectional or a polymorphic VT that is associated with a structurally normal heart and is characteristically precipitated with exercise and emotional stress. Management of CPVT consists of β -blockers, with ICD implantation for those experiencing cardiac arrest, sustained VT or syncope despite maximal therapy.

Idiopathic Left Ventricular Tachycardia

This is the only VT that is relatively *narrow complex* (**Fig. 11**). QRS complex is *narrow*, typically 100 ms, as the impulse travels through the fascicles, which is a rapid conductor. It is the only VT that is sensitive to verapamil. The most common variety arises from the left posterior fascicle and thus the QRS shows an incomplete right bundle branch block (RBBB) with left axis. Given that RBBB should have a right axis, this ECG pattern is classical.

Treatment Idiopathic left ventricular tachycardia (ILVT) is mostly stable and therefore gives adequate time to diagnose and treat.

Figure 11 Narrow QRS tachycardia at approximately 140 bpm. The QRS duration is < 120 ms but wider than what a usual QRS in supraventricular tachycardias (SVTs). There is an incomplete RBBB with left axis that is classical of fascicular ventricular tachycardia (VT). The arrows point to the P waves that distort the shape of ST-T segment as they are dissociated from the ventricle (VA dissociation). The QRS onset is very sharp that also points to its fascicular origin as myocardial VTs show a gradual onset because of the slow conduction

In general CCB should not be given for a VT and thus any wide QRS tachycardia. Acutely, lidocaine (1.0 mg/kg/dose over 1–2 min) may be given followed by lidocaine infusion. If diagnosis is certain, IV verapamil or diltiazem can be given. IV Amiodarone is also effective but is rarely needed. DCCV can be done if all measures fail. RF ablation is treatment of choice in older children and adults.

BRADYARRHYTHMIAS

Bradyarrhythmia may occur due to either a defect in impulse formation or conduction.

- Disorders of impulse formation
 - Sick sinus syndrome (sinus pauses, sinus arrest)
 - Nonspecific, scar-like degeneration of the heart's conduction system, often age-related (not common in children)
 - Familial, hypothyroidism, drugs
 - Congenital heart diseases associated with isomerism and situs ambiguus
 - Postoperative, e.g., following a Glenn shunt, Senning operation.
- Disorders of impulse conduction
 - Sinus node conduction abnormalities
 - AV blocks: First degree, second degree and complete heart block. It maybe congenital, postoperative, or associated with congenital heart diseases like corrected transposition of great arteries (cTGA), AV septal defects
 - Diphtheritic myocarditis, Lyme's disease, viral myocarditis
 - Hyperkalemia
 - Drugs like CCB, β -blockers, digoxin, tricyclic antidepressants can also lead to blocks
 - Poisoning with aluminum phosphide, yellow oleander.

ATRIOVENTRICULAR BLOCK

A disorder of conduction of impulse from atrium to ventricles is due to AV block which is classified according to the severity of conduction abnormality. In mild cases, only prolongation of PR interval occurs (first degree AV block), in more severe cases, some of the atrial impulses are not conducted into the ventricles (second

degree AV block) and in most severe cases, none of the atrial impulses are conducted to the ventricles (complete AV block).

COMPLETE HEART BLOCK

Complete heart block is the most common bradycardia (after sinus bradycardia) in a child (**Fig. 12**). In general, the heart is structurally normal, though it is well known to occur in cTGA. Although literature suggests that 50% of mothers with children having congenital CHB (CCHB) will have manifest connective tissue disease especially systemic lupus erythematosus (SLE) our experience is not the same. We have rarely seen manifest SLE in the mothers but more than 90% have positive anti-Ro and anti-La antibodies. Conversely, firstborn of mothers with SLE or positive antibodies have an incidence of CHB of 1–2%. The risk of recurrence in a subsequent child increases to 10–16%. The CHB usually occurs in the second or third trimester and may be preventable by immunosuppressants. Once CHB has occurred, it does not resolve, though the ventricular rate maybe increased by sympathomimetics.

The newborn with CCHB may have varied manifestations but is often asymptomatic. This primarily depends on the origin and stability of the escape rhythm that mostly comes from AV junctions. With structural heart disease the child may have significant cardiomegaly and CHF. Symptoms like CHF, seizures due to intermittent asystole or fast polymorphic ventricular tachycardia, failure to thrive are obvious indications for pacing. The decision to pace becomes more difficult when the child is asymptomatic. Over 75% of children with asymptomatic CCHB would eventually need a pacemaker by the age of 20.

Indications for pacing in asymptomatic congenital complete heart block are summarized in **Table 6**. Pacemakers in children can be implanted epicardially or endocardially depending on the weight of the child, access site, risk of a systemic embolization etc. Children with hemodynamically significant VT may need ICDs. Devices like pacemaker and ICD in children are a highly specialized area but give a near normal life to the child. It is important for pediatricians to make the child feel normal and allow them all activities. In general, current pacemaker batteries are good enough to last for at least 10 years. However, this is a function of the current needed, paced heart rates, duration of pacing, single or double

Figure 12 Three-channel Holter recording of a 13-month-old child with complete heart block (CHB). Note the P waves are marching through the QRS complexes. To diagnose CHB the atrial rate should be faster than ventricular rate, the PR interval will change constantly and the ventricular rate will be constant. Since ventricle does not get any input, some part of the junction or the ventricle starts to fire to keep the heart going. Lower the origin of the escape rhythm, lower is its rate and broader is the QRS. In this child the maximum QRS duration is 120 ms which is way longer than the normal range at this age of 33–78 ms. This implies the rhythm is coming from the ventricle or the bundles and one cannot rely on them. This is a definite indication for a permanent pacemaker implantation

Table 6 Indications for pacing in asymptomatic congenital complete heart block (CCHB)

• QRS of the junctional escape rhythm is wide for the age of the child
• Mean daytime awake ventricular rate < 50/min in infants and children, < 55/min in neonates and < 65/min in the presence of structural heart disease. Sleep rates < 30/min may also be considered as an indication for pacing
• Cardiomegaly not attributable to other reasons
• Frequent ventricular ectopy, NSVT and presence of short coupled VPBs
• Poor chronotropy
• CHF
• Prolonged QTc > 480 ms or absolute QT > 600 ms

Abbreviations: CHF, congestive heart failure; NSVT, nonsustained ventricular tachycardia; VPBs, ventricular premature beats.

chamber, etc. In the current era, no child should die because of inability to give a pacemaker.

SUDDEN CARDIAC DEATH/SUDDEN CARDIAC ARREST IN CHILDREN

Sudden cardiac death or sudden cardiac arrest (SCA) is defined as cardiac arrest occurring within an hour of onset of symptoms in a person with known or unknown heart disease—the timing and mode of death should be unexpected. The term SCD has a limitation as a large number of these patients (predominantly in the developed world) now survive the immediate event by aggressive and efficient resuscitation. This led to a paradoxical term called as SCD survivors and therefore SCA is a preferred term now. There are several causes of SCA that are listed in **Table 7**.

CONCLUSION

We have tried to give a broad overview of cardiac dysrhythmias in children. It is important for pediatricians to understand the

genesis and mechanism of arrhythmias. It is equally important not only to recognize the arrhythmia going on but try and find the type/mechanism. Thus, when confronted with a narrow QRS tachycardia one should be able to diagnose whether it is sinus tachycardia, AVRT, EAT or atrial flutter/fibrillation. This is important because it determines the immediate treatment and the long-term management. Catheter ablation has provided a *cure* for several of these arrhythmias, unlike most other chronic diseases that can be only controlled on drugs. Cardiac devices are getting more and more sophisticated, smaller in size and affordable. More and more children will need such devices in the future as results and numbers of surgical procedures for congenital heart disease increase. India and many other developing nations face a severe shortage of experts in managing these children and we hope this chapter can inspire some of you to choose this specialty.

Table 7 Cardiac disorders predisposing to sudden cardiac death (SCD)

Structural/functional
• Hypertrophic cardiomyopathy
• Coronary artery anomalies
• Dilated cardiomyopathy or restrictive cardiomyopathy
• Myocarditis
• Left ventricular outflow tract obstruction
• Arrhythmogenic right ventricular cardiomyopathy
• Postoperative congenital heart disease
Electrical
• Long QT syndrome
• Wolff-Parkinson-White syndrome
• Brugada syndrome
• Catecholaminergic polymorphic ventricular tachycardia
• Short QT syndrome
• Complete heart block
Other
• Drugs and stimulants; some prescription medications
• Primary pulmonary hypertension

IN A NUTSHELL

1. Cardiac arrhythmias (preferably called as dysrhythmias) are omnipresent and pediatricians of today have to improve upon their ECG reading, interpretation and management.
2. In general nonsustained arrhythmias, even ventricular arrhythmias to a certain extent are benign, if the underlying heart is normal, structurally and electrically.
3. Arrhythmias should be treated only if, they are causing symptoms or leading to hemodynamic problems such as hypotension, congestive heart failure, syncope, etc.
4. Tachyarrhythmias are currently divided into two major groups that are supraventricular and ventricular tachyarrhythmias. Most tachyarrhythmias occur due to re-entry.
5. A 12-lead ECG, preferably in rhythm format (12 × 1), should always be done when the patient comes with a sustained arrhythmia. Every effort should be made to record the ECG while giving intravenous adenosine.
6. Atrioventricular re-entrant tachycardia (AVRT) due to a manifest or concealed pathway is the most common cause of sustained cardiac arrhythmias in infants and children. WPW syndrome, i.e., manifest pre-excitation with symptoms can very occasionally lead to sudden cardiac death (SCD) at the rate 0.05%/year.
7. DC cardioversion (DCCV) should always be ready when treating any sustained arrhythmia. Even intravenous adenosine can lead to ventricular fibrillation in an occasional patient of WPW syndrome.
8. Sustained tachyarrhythmias may lead to a reversible *dilated cardiomyopathy like picture*, that normalizes once the tachycardia is taken care of. Manifest pre-excitation by itself can lead to left ventricular dysfunction due to the dys-synchrony caused by it.
9. Prophylactic drug therapy for most tachyarrhythmias should be used only for symptomatic patients having frequent sustained arrhythmias. It is not necessary to give pills to a child everyday to prevent an SVT that occurs once or twice a year.
10. Amiodarone oral and intravenous is a toxic drug that should not be used or, if unavoidable, then given for as short a time as possible. Oral amiodarone should not be used for a benign SVT in a normal heart.
11. Flecainide, propafenone and sotalol are highly effective drugs in preventing several arrhythmias. However, these should only be used by doctors who are familiar with its use and in patients whose ECG can be monitored on a regular basis.
12. Catheter ablation has revolutionized the management of tachyarrhythmias with very high success rates, typically over 95% in most SVTs and VTs with normal hearts. It has been used successfully even in neonates, if indicated.
13. Diagnostic electrophysiological studies have a limited role in the current era especially for bradycardias and blocks.
14. Sudden cardiac death/sudden cardiac arrest (SCD or SCA) is not an uncommon event in infants and children.
15. Primary electrical diseases of the heart such as long QT syndrome, Brugada syndrome, CPVT, short QT syndrome, Early repolarization syndrome, idiopathic VF, etc., are now called as *channelopathies* as all these defects are linked to the ion channels in the heart. They are frequently missed and one important rule is to get an ECG done for every patient having frequent *seizures*. Family history of sudden death should always be probed with due diligence in children with syncope, seizures.

Chapter 40.38

Cardiac Emergencies

Umesh Dyamenahalli

Though cardiovascular emergencies of life-threatening nature are infrequent in children, adequate awareness, high index of suspicion and preparedness for arriving at precise early diagnosis and instituting appropriate and timely management are necessary to minimize morbidity and the mortality. Delay in recognition and optimal management can lead to devastating outcomes. With evolution and timely improved interventions and perioperative care, the survival of these patients has improved remarkably. Newborns, infants and children with heart disease may present to emergency facilities as undiagnosed congenital heart disease (CHD) with complications, after palliative surgical procedures, after definitive repair, or with acquired cardiovascular disorders.

Pediatric cardiac emergencies (**Table 1**) are due to variety of pathology including imminently life-threatening CHDs, arrhythmias, infections, inflammatory conditions, familial conditions and trauma. Other pediatric cardiac emergencies presenting as chest pain, syncope and near missed cardiac deaths are beyond the purview of this chapter.

EMERGENCY EVALUATION OF NEONATES AND INFANTS WITH SUSPECTED CONGENITAL HEART DISEASE

Patients with significant CHD present in the first few days and weeks after birth with signs and symptoms of cyanosis, shock, congestive heart failure or significant murmur. It is not uncommon to find newborns with ductal dependent lesions appearing to be normal

on routine newborn examination after birth in the first few days to be sent home but only to return with serious and life-threatening clinical findings that require immediate intervention. Urgent assessment, initial stabilization and expeditious consultation is essential when severe, potentially lethal CHD is suspected in critically ill neonates who present with shock, cyanosis, or pulmonary edema.

Clinical Evaluation

Evaluation of a neonate or an infant with suspected CHD includes thorough history and physical examination which must essentially include looking for cyanosis and careful checking of the quality of arm and leg pulses along with four limb blood pressure measurements, both of which are considered vital for early detection of critical or severe CHD. If there is diminished or absent peripheral pulses and perceptible difference in arm and leg pulses, ductal dependent systemic flow lesions such as critical aortic stenosis, coarctation of aorta (CoA), interrupted aortic arch and hypoplastic left heart syndrome must be suspected. Chest radiographs, electrocardiogram (ECG) and if indicated *hyperoxia test* and echocardiograms are an extension of initial assessment. Pulse oximetry is helpful to detect mild desaturation in patients with ductal-dependent lesions, as mild desaturation may be difficult to appreciate visually.

Neonatal Cardiac Emergencies due to Ductal Dependent Congenital Heart Disease

It is important to realize that any infant less than or equal to 6 weeks who presents in shock or profoundly cyanotic might be secondary to closure of the ductus arteriosus in conjunction with a right- or left-sided obstructive cardiac lesion. The two most important presentations of life-threatening neonatal cardiac emergencies are: (1) onset of acute hypoxemia within or after 24 hours of birth manifest clinically as worsening cyanosis, and if untreated

Table 1 Cardiac emergencies based on age and etiology

Structural congenital heart diseases (CHDs)	
Neonates: (A) Ductal dependent (Dd) CHDs	
• Duct dependent pulmonary blood flow (presents with severe cyanosis, acidosis, reduced feeding and motor activities)	TOF, PAtr with VSD, PAtr with intact septum, critical PS, TA, Ebstein anomaly of TV, heterotaxy (most often)
• Duct dependent systemic blood flow (presents with shock, feeble pulse, peripheral and/or minimal central cyanosis)	Neonatal CoA, critical AS, HLHS, interrupted aortic arch, heterotaxy (less common)
Neonates: (B) Nonduct dependent cyanotic CHDs	
• Cyanosis often with features of heart failure	Truncus Art., TAPVR, d-TGA (D-TGA is not duct dependent lesion, however, PDA does improve mixing at atrial level by increasing pulmonary venous return, especially with an intact ventricular septum)
• Severe cyanosis and respiratory distress	Obstructed type of TAPVR, pulmonary hypertension
• Neonatal cardiac dysfunction (presenting as CHF)	Dilated cardiomyopathy/myocarditis, severe hypertrophic cardiomyopathy, rarely ALCAPA, complete congenital heart block
• Fetal and neonatal arrhythmias	SVT (re-entry narrow complex tachycardia), VT, complete congenital heart block, atrial flutter
Cardiac emergencies in postneonatal period, infancy and childhood	
Those presenting with CHF	Large left to right shunt—large VSD, PDA; large common mixing lesions—truncus arteriosus and ALCAPA
Pericardial effusion	
Cardiac conditions associated with other congenital anomalies	
Tetralogy of Fallot with hypercyanotic spells	
Postoperative conditions—functional and structural abnormalities along with patient specific problems	

Abbreviations: TOF, tetralogy of Fallot; PAtr, pulmonary atresia; PS, pulmonary stenosis; TA, tricuspid atresia; Truncus Art, truncus arteriosus; TAPVR, total anomalous pulmonary venous return; d-TGA, d-transposition of the great arteries; CHF, congestive heart failure; CoA, coarctation of aorta; AS, aortic stenosis; ALCAPA, anomalous origin of the left coronary artery from the pulmonary artery; VSD, ventricular septal defect; PDA, patent ductus arteriosus; HLHS, hypoplastic left heart syndrome.

develops acidosis (**Table 1-neonate A**) and (2) shock such as state with feeble pulses, poor peripheral circulation, acidosis and decreased activity and responsiveness (**Table 1-neonate B**).

Newborn with Cyanosis and Acidosis

The first clinical scenario (**Table 1-neonate A**) indicates the possibility of a CHD with right ventricular outflow tract obstructive lesions (extreme tetralogy, critical pulmonary stenosis or atresia, tricuspid atresia, d-transposition of great arteries with inadequate mixing) where presence of a patent ductus arteriosus (PDA) is crucial to maintain better pulmonary blood flow and hence improved arterial oxygen saturation sufficient to keep the neonate in stable condition and alive. These conditions are hence called ductus dependent pulmonary blood flow conditions. The neonate becomes acutely symptomatic when the ductus arteriosus closes after birth with the development of the earlier symptomatology.

The *primary life-saving resuscitative step* in such a scenario is to reopen the ductus arteriosus or prevent its further closure by giving intravenous (IV) infusion of prostaglandin E1 (PGE1) (starting dose: 0.05–0.1 µg/kg/min, may go up to 0.2 µg/kg/min, in the absence of satisfactory response in saturation and acid-base parameters, and cautiously wean the dose to the effective minimum maintenance dose of 0.01 µg/kg/min). The use of PGE1 in an effort to reopen ductus is acceptable in the first 30 days of life. Other important resuscitative steps are listed as follows:

1. Oxygen administration so as to keep the saturations between 75% and 85%, if necessary intubation and ventilation.
2. Improving preload by expansion of blood volume using either 10 mL/kg of 0.9% saline or 5% albumin IV bolus with repeated boluses till liver edge becomes palpable.
3. Correcting acidosis and maintaining the acid-base equilibrium. If necessary IV sodium bicarbonate (1 mEq/kg of 4.2 5% solution). If the pH is more than 7.25, there is no need correct the acidosis rapidly by giving bicarbonate—please see oxygen dissociation in acidic pH.
4. Correcting other possible metabolic derangements such as hypoglycemia, hypocalcemia.
5. Empiric antibiotics, if sepsis is suspected.
6. Judicious use of inotropes/vasopressors, only when indicated to maintain adequate systemic perfusion.
7. Making concurrent efforts to evaluate the neonate and diagnose the underlying structural CHD with the help of echocardiography (Echo) performed by pediatric cardiologist and cardiac centers for appropriate surgical intervention.
8. Intubation with assisted ventilation under sedation with or without paralysis to improve oxygenation and limit metabolic demands.

Newborn with Heart Failure

The second clinical scenario (**Table 1-neonate B**) indicates the possibility of a CHD with left-sided outflow tract obstructive lesions, such as hypoplastic left heart syndrome (HLHS), critical mitral or aortic valve stenosis or atresia, CoA, interrupted aortic arch, where presence of a PDA is crucial to maintain adequate systemic arterial circulation to keep the neonate alive. These conditions are therefore called ductus dependent systemic blood flow conditions. The neonate becomes acutely symptomatic when the ductus arteriosus closes after birth with the development of the earlier symptomatology.

The life-saving resuscitative steps mentioned earlier are the same starting with immediate admission into neonatal intensive care unit (NICU) set-up with prostaglandin E1 infusions, volume resuscitation with frequent IV aliquots of 5–10 mL of 0.9% normal saline or 5% albumin, if readily available, and oxygen to maintain saturation around 75–85% and all the other steps enumerated

earlier. Long-term survival is possible, if these steps are followed efficiently till the stabilized neonate is safely entrusted to the care of safe surgical experts. Here, it is very important improve cardiac output and avoid measures which might increase pulmonary flow.

Functional Single Ventricle

A wide anatomic variety of lesions are usually associated with hypoplasia or atresia of atrioventricular, semilunar valves or outlets sharing similar physiology of complete mixing of the systemic and pulmonary venous blood. A few others with good sized valves are unable to achieve biventricular circulations because of associated malattachment, or straddling of the valves. On an emergency basis, it is imperative and urgent to assess and understand the following parameters: (1) Is the underlying CHD a ductal dependent condition; (2) Is cardiac output adequate not to endanger survival of the neonate; and (3) Presence of evidence for specific known syndromes and/or involvement of other organs. In addition precise understanding of the unique physiology of patients born with complex CHDs with single functioning ventricle is required to effective management.

Some of the examples of CHDs with single functioning ventricle physiology are: (1) hypoplastic left heart syndrome, (2) tricuspid atresia, (3) unbalanced atrioventricular canal defects, (4) double outlet right ventricles, and (5) double inlet ventricles. Some of these patients may have adequate pulmonary and systemic flow, while in others the pulmonary or systemic blood flow depends on the patency of the ductus arteriosus. The common finding among these defects is that the heart has only one effective functioning ventricle taking extra workload (pressure and volume overload) in pumping blood to both the body (systemic circulation) and lungs (pulmonary circulation). Effective initial management is vital to minimize other organ dysfunction and prevent cardiorespiratory arrest and to improve survival outcomes.

CRITICAL CONGENITAL CARDIAC DISEASES

Most of these conditions have been already discussed in detail in respective chapters. Here, only the emergency management part is described.

Coarctation of Aorta (Critical)

Newborns with critical CoA invariably present with the spectrum of profound shock, metabolic acidosis and multiple organ dysfunction. The pulse difference between upper and lower limbs may not be present, if there is myocardial dysfunction. Differential cyanosis may be present, because of right to left shunt across PDA in presence of pulmonary hypertension. Neonates and infants with CoA can present with progressive congestive heart failure, usually before 4 months of age. Administration of prostaglandin E1 infusion in newborns and other life-saving supportive therapy is necessary; followed by referral for appropriate assessment and surgical intervention.

Hypoplastic Left Heart Syndrome

Hypoplastic left heart syndrome is characterized by poor peripheral perfusion with cyanosis, pallor, and difficult to feel peripheral pulses (unless there is PDA and balanced systemic and pulmonary flow). Systemic saturations can be in the range of 70s–80s. Echo is essential for the diagnosis. Prostaglandin E1 infusion (0.01–0.1 µg/kg/min) to preserve the patency of the ductus arteriosus, and to maintain adequate systemic circulation is the main stay of initial management. It is essential to avoid measures that could decrease pulmonary vascular resistance and increase pulmonary blood flow [i.e., high fraction of inspired oxygen (FiO₂), and hyperventilation]. This is to be followed by appropriate surgery.

Tetralogy of Fallot

Neonates with tetralogy of Fallot (TOF) having pulmonary atresia present with severe cyanosis and are ductus dependent for their pulmonary blood flow to minimize severe cyanosis. The immediate management will be directed to keep the ductus open. In infants and children, the most common emergency is hypercyanotic spell (Tet spells). These occur in infants and children with unrepaired TOF and other cardiac defects with ventricular septal defect and narrow pulmonary outflow tract (tricuspid atresia and normally related great arteries). Children with episodes of self-limiting cyanotic spell should be considered for early surgical intervention. Tet spells are a medical emergency deserving emergency management.

Management of Cyanotic Spell

These spells are usually seen between the ages of 1 month and 12 months, in the morning, after waking from sleep; defecation, agitation, dehydration, crying and invasive procedures without proper sedation are usual precipitating factors. The spell is manifested by increase in rate and depth of respiration (hyperpnea) and increasing cyanosis; it may progress to limpness and loss of consciousness. Examination reveals an agitated and cyanotic infant and a previously heard cardiac murmur of right ventricular outflow obstruction is either absent or markedly decreased in intensity during the spell. The mechanism causing the spells is not completely understood; it is likely due to spasm of the right ventricular outflow tract (infundibulum) resulting in markedly decreased pulmonary blood flow along with right-to-left shunting across the ventricular septal defect (VSD). Infundibular spasm may be precipitated by acute increase in endogenous catecholamines. Management is outlined in **Table 2**.

D-Transposition of the Great Arteries

D-Transposition of the great arteries (TGA), a lethal and relatively frequent malformation, accounting for upto 5–7% of critical CHD. These patients usually presents with cyanosis with the saturations in 60s–70s within 2 days of life. Degree of desaturation depends on intracardiac mixing, effective pulmonary flow and cardiac output. They breath comfortable but tachypneic. Supplemental oxygen does not improve saturation. Prostaglandin improve saturations by

increasing pulmonary flow, therefore increased pulmonary venous return results in better intracardiac mixing via patent foramen ovale or atrial septal defect (ASD). Usually, these newborns have normal pulses and blood pressures. If there is no intracardiac mixing (shunt) without any ASD or VSD severe cyanosis persists with severe hypotension despite prostaglandin infusion and PDA. These neonates will require balloon atrial septostomy to facilitate intracardiac mixing at atrial level.

Obstructive Total Anomalous Pulmonary Venous Return

Pulmonary veins drain anomalously into a systemic venous structure rather than directly into left atrium. There is common collecting pulmonary venous confluence. Obstructive type of total anomalous pulmonary venous return (TAPVC) is symptomatic soon after birth with severe respiratory distress and cyanosis, less commonly with signs of low cardiac output. Cardiac examination shows prominent right ventricular impulses and loud P₂, with or without a murmur—either pulmonary flow ejection murmur or tricuspid regurgitant holosystolic murmur. Liver usually is enlarged. Echo is diagnostic. Supportive therapy, likely need intubation and ventilation and right heart support. Prostaglandin infusion is usually not necessary.

Ebstein Anomaly

It can be challenging to treat severe Ebstein's anomaly with severe tricuspid regurgitation. Initially, prostaglandin use may be necessary to maintain the ductal patency, however, one needs to take the measures to lower the pulmonary vascular resistance (supplemental O₂, minimize lung atelectasis, if necessary nitric oxide may be needed).

HEART FAILURE AS EMERGENCY

Details of heart failure and its management have been already discussed in detail in the previous chapter. Congestive heart failure may occur secondary to structural CHDs, and other genetic, metabolic, nutritional, electrophysiological and infective causes of myocardial dysfunction. Causes of heart failure according to the age at presentation are listed in **Table 3**. Drugs used for treating heart failure are summarized in **Table 4**.

Table 2 Management of hypercyanotic or Tet spells

<i>Objectives of therapy</i>	
To improve pulmonary flow and to minimize alveolar hypoxemia; to increase venous return, to decrease catecholamine surge	
<i>Management steps</i>	
1.	Supplemental oxygen (facemask) (temporarily discontinued, if baby gets more agitated and restless)
2a.	Efforts to be made to calm the baby
2b.	Knee to chest (by helping the parent to hold over the shoulder with knees bent with supplemental oxygen)/squatting position in older infant – (Benefits: It increases systemic resistance and also improves venous return)
3.	Sedation (intramuscular or intravenous morphine 0.1 mg/kg) (decreases catecholamine surge, heart rate and respiratory rate)
4.	Volume expansion: Normal saline (crystalloid) fluid bolus: 10–20 mL/kg by rapid IV push Augments preload and to be given prior to the following drugs which may induce hypotension
5.	Persistent cyanosis: Administration of phenylephrine 5–20 µg/kg/dose or norepinephrine infusion 0.05–2 µg/kg/min agents to increase systemic resistance and reduce the right-to-left shunt
6.	Persistence of cyanosis: IV beta-blockers—esmolol infusion 50–300 µg/kg/min or propranolol 0.1 mg/kg dose ultrashort-acting cardioselective beta-blocker (reduces dynamic muscular RVOT stenosis and increases PBF)
7.	No response with deterioration in saturation: Intubation and ventilation with correction of electrolyte disturbances and metabolic acidosis
8.	Emergency systemic to pulmonary shunt or even extracorporeal circulation (ECMO) support is occasionally indicated for refractory hypercyanotic spells

Abbreviations: RVOT, right ventricular outflow tract; PBF, pulmonary blood flow.

Table 3 Causes of heart failure according to age of presentation

First day within few hours after birth	<ul style="list-style-type: none"> Mostly noncardiac causes such as myocardial dysfunction secondary to severe asphyxia, hypocalcemia, hypoglycemia, severe anemia <i>Cardiac causes:</i> Severe tricuspid regurgitation, Ebstein's anomaly, severe ventricular outflow obstructive lesions, HLHS, large left to right shunts in preterms, arrhythmias such as SVT and complete heart block
First week	HLHS, TGA, coarctation of aorta, systemic A-V fistulas, thyrotoxicosis in newborns, a few inherited metabolic cardiomyopathies such as Pompe's disease; plus causes mentioned earlier
1 week to 1 month	Coarctation of aorta, TGA, large left to right shunts such as PDA, VSD (especially in preterms), systemic A-V fistulas, TAPVC (obstructive truncus arteriosus), SVT, endomyocardial fibroelastosis, metabolic, inherited and acquired cardiomyopathies including myocarditis, acute cor pulmonale, fluid overload syndromes
1–3 months	TGA, TAPVC, truncus arteriosus, coarctation of aorta, others as earlier
3–6 months	Large left to right shunts such as PDA, VSD; systemic A-V fistulas SVT, endomyocardial fibroelastosis, metabolic, inherited and acquired cardiomyopathies including myocarditis, TGA, TAPVC, truncus arteriosus
Beyond 6 months	Large left to right shunts such as PDA, VSD; systemic A-V fistulas SVT, endomyocardial fibroelastosis, metabolic, inherited and acquired cardiomyopathies including myocarditis, pulmonary venous anomalies, TAPVC, truncus arteriosus

Abbreviations: HLHS, hypoplastic left heart syndrome; PDA, patent ductus arteriosus; TGA, d-transposition of the great arteries; TAPVC, total anomalous pulmonary venous return; VSD, ventricular septal defect; SVT, supraventricular tachycardia.

Table 4 Basic principles of treatment of congestive heart failure

<i>Drugs selected in the treatment of congestive heart failure in children</i>	
Diuretics	Furosemide 1 mg/kg/dose (usual dose) IV or oral either twice a day or often as q 6h Spironolactone 1 mg/kg/dose twice a day
ACE inhibitors	Captopril, enalapril
<i>Inotropes to increase myocardial contractile efficiency: Digitalis and nondigitalis inotropic agents</i>	
Digoxin	Commonly used inotropic drug in the past, but now judiciously used with availability of other alternative drugs
Dopamine	5–10 µg/kg/min or epinephrine 0.03–0.1 µg/kg/min
Amrinone Milrinone Levosimendan	Phosphodiesterase inhibitors used as inotropes 0.3–1 µg/kg/min infusion with or without loading dose; 30–40 times more potent than amrinone Extremely promising new drug being increasingly used and evaluated in young children
<i>Beta-blockers therapy</i>	
Prostaglandin E1 (PGE1)	Neonates with ductal dependent systemic perfusion [0.05–0.1 µg/kg/min (effective lowest dose) up to 0.4 µg/min in unresponsive cases] See earlier
L-Carnitine	
General supportive measures	Respiratory support as needed Correct acidosis or metabolic derangements and maintain normal electrolytes Treatment of infections Treatment of anemia or other coexisting risk factors
Other options in refractory CHF due to significant cardiac dysfunctional states	
LVA devices	Increasing use of this significant advance in management of refractory failure due to systemic cardiac dysfunction and prevention of sudden cardiac death
IABP ECMO	Pre- and postoperative preparatory stages in certain CHDs and AHDs: Extensively used prior to major complex cardiac surgeries such as heart transplantation
Ventricular assist devices	Still under investigative consideration in children as an alternative to transplantation or a preparatory option
<ul style="list-style-type: none"> Cardiac resynchronization with biventricular pacing as an emergency therapy in chronic refractory CHF Implantable cardiac defibrillator—Considered in those surviving sudden cardiac arrest; programmed to respond when the heart rate goes beyond a certain preset rate 	
Cardiac transplantation	Cardiomyopathies refractory to medical and other supportive measures; mainly in dilated cardiomyopathy, others such as restrictive, hypertrophic, arrhythmogenic RV, dysplastic cardiomyopathies
Appropriate definitive surgical management as indicated in refractory cases after functional and hemodynamic stabilization with measures mentioned earlier.	

Abbreviations: LVA devices, left ventricular assist devices; ECMO, extracorporeal membrane oxygenation; IABP, intra-aortic balloon pump; CHDs, congenital heart diseases; AHDs, acquired heart diseases; ACE, angiotensin converting enzyme; CHF, congestive heart failure.

Myocarditis, Dilated Cardiomyopathy, Hypertrophic Cardiomyopathy and other Metabolic Myocardial Dysfunction Syndromes

Initial supportive and aggressive heart failure therapy is required. Appropriate specific therapy and timely mechanical circulatory support may be necessary to support and sustain till transplantation or recovery.

CARDIAC TAMPONADE

Cardiac tamponade is life-threatening, slow or rapid compression of the heart due to the pericardial accumulation of fluid, pus, blood, clots or gas, as a result of effusion, trauma, or rupture of the heart. Because the causes of pericardial disease and thus of tamponade are diverse, clinicians must be aware of the problem and the diagnosis. Tamponade is not uncommon in postoperative period. Pericardial effusion is the major cause of tamponade. The primary abnormality is rapid or slow compression of all cardiac chambers as a result of increasing intrapericardial pressure. Clinical features of tamponade vary, depending on the cause and rate of accumulation. They are usually tachycardic and a key diagnostic clinical finding, pulsus paradoxus, conventionally defined as an inspiratory systolic arterial blood pressure fall of 10 mm Hg or more during normal breathing is often palpable in proximal arteries (e.g., brachial). Chest X-ray shows cardiomegaly. ECG shows sinus tachycardia and low QRS voltages. Doppler echo is diagnostic. Management consists of maintaining the intravascular volume and avoiding excessive diuresis. Specific treatment is drainage of the pericardial fluid by needle pericardiocentesis or surgical drainage.

KAWASAKI DISEASE AS EMERGENCY

Kawasaki disease does not usually present as a critical emergency; however, during the acute phase of the disease, in addition to coronary arteritis, pericarditis, myocarditis, and valvar heart disease can develop. Myocarditis can lead to myocardial dysfunction and children can present hypotensive and in cardiogenic shock. Arrhythmias can be associated as well as PR prolongation and nonspecific ST and T wave changes noted on ECG. Specific treatment consists of intravenous immunoglobulin (IVIG) and high dose aspirin.

ARRHYTHMIAS

Supraventricular tachycardia (SVT) is the most frequent arrhythmia in the neonatal period and childhood in children with structurally normal hearts. Further details of arrhythmias and management have been already discussed in a separate chapter in this section.

IN A NUTSHELL

1. Patients with significant congenital heart disease present in the first few days and weeks after birth with signs and symptoms of cyanosis, shock, congestive heart failure or significant murmur.
2. The two most important presentations of life-threatening neonatal cardiac emergencies are: onset of acute hypoxemia after 24 hours of birth manifesting clinically as worsening cyanosis and shock.
3. Onset of acute hypoxemia after 24 hours of birth manifesting clinically as worsening cyanosis and acidosis suggests a right outflow tract obstruction.
4. Shock like state with feeble pulses, poor peripheral circulation, acidosis and decreased activity and responsiveness suggests a left outflow tract obstruction.
5. Prostaglandin infusion can be life-saving in both these situations as these lesions are mostly ductus dependent.

Chapter 40.39

Surgical Considerations in Congenital Heart Diseases

R Benedict Raj, S Srinivasan

The incidence of congenital heart disease (CHD) has shown a very slow increasing trend over the last century. In the last 20 years, the results of treatment and cardiac surgery have become sufficiently reliable, affordable and safer option that more children have access to total correction. Major types of surgeries for CHD are listed in **Table 1**.

PALLIATIVE PROCEDURES

Palliative shunt procedures to increase the pulmonary blood flow are outlined in **Table 2**. Modified Blalock-Taussig (BT) shunt is a temporary initial palliative anastomotic procedure of shunting of subclavian arterial blood to the pulmonary artery to augment pulmonary blood flow in neonates. With the advent of better neonatal results, the indications for a modified BT shunt are becoming fewer. In comparison to the BT shunt (which acts as a left to right shunt) that increases volume load to the systemic ventricle and can cause unwanted dilatation, the Glenn shunt reduces the blood that reaches the ventricles by diverting a significant quantity to the pulmonary circulation. The success of this operation depends on good size pulmonary arteries and low pulmonary artery (PA) pressures (<15 mm Hg).

Fontan Procedure

A univentricular Fontan repair is the procedure for all cyanotic children with cardiac malformations with a single functional ventricle (in the absence of either an adequate atrioventricular valve or pumping chamber and without any possibility of two ventricular repair). Indications include tricuspid atresia, pulmonary atresia with intact ventricular septum, double inlet ventricle, hypoplastic left heart syndrome and in other complex CHDs with high surgical risk morbidity.

Children with earlier bidirectional Glenn shunt (BDGS) palliation remain well palliated for 4–5 years. When the child grows up and outgrows the quantity of blood that returns from the upper body in a reasonably well done BDGS, the need for additional pulmonary blood flow (PBF) is met by a palliative extracardiac Fontan operation. This diverts inferior vena cava (IVC) blood to the lungs by placement of an extracardiac 18–22 mm diameter PTFE conduit (polytetrafluoroethylene) independent of right heart contractions. The most important determinants of success are ventricular function and pulmonary vascular resistance (PVR).

Pulmonary Artery Banding

In children who have a cardiac lesion with increased PBF and cannot be corrected without risk as in very tiny babies, banding of the PA is a technique of reducing the PBF and protecting the lungs from increased blood pressure (pulmonary arterial hypertension [PAH]). The indications for PA banding are becoming less with increased success in corrective operations. This includes Swiss cheese ventricular septal defect (VSD), single ventricle with increased PBF and training a regressed left ventricle (LV) for arterial switch operation (ASO). The PA band reduces pulmonary pressures over a period of time to less than 15 mm Hg, this prepares the pulmonary circulation to accept a BDGS.

Table 1 Surgeries in congenital heart disease (CHD)

Corrective surgeries	Postsurgical residual issues	None	ASD, VSD, PDA, AP window TOF repair (without pulmonary valvotomy)
		Possible	Repair of AV canal, TAPVC, CoA, arterial switch operation
		Often present	Repair of TOF with pulmonary patch, placement of Conduit, Senning operation
Palliative surgeries	Early life saving, complication preventing first step procedure prior to undertaking total or near total corrective surgery later		Modified Blalock-Taussig shunt (BT Shunt) Bidirectional Glenn shunt (BDGS) Fontan procedure Pulmonary artery banding
Neonatal surgeries	Conditions		
	Ductus dependent PBF	Modified BT shunt for neonatal tetralogy, pulmonary atresia, single ventricle with reduced pulmonary blood flow	
	Ductus dependent SBF	Repair CoA, arch interruption	
	D-TGA TAPVC	Arterial switch operation (ASO) TAPVC repair	

Abbreviations: ASD, atrial septal defect; VSD, ventricular septal defect; PDA, patent ductus arteriosus; TOF, tetralogy of Fallot; AP, aortopulmonary; AV, atrioventricular; CoA, coarctation of the aorta; TAPVC, total anomalous pulmonary venous connection; PBF, pulmonary blood flow; D-TGA, D-transposition of the great arteries; SBF, systemic blood flow.

Table 2 Palliative surgeries

Palliative shunt procedures to increase the pulmonary blood flow		
Blalock-Thomas-Taussig (BTS)	End-to-end anastomosis between the SCA and PA	
Modified BTS	Use of prosthetic graft	Creation of anastomosis between subclavian artery and pulmonary artery
Bidirectional Glenn	Ligation of SVC at its entrance to RA; end-to-side anastomosis between SVC and right PA with ligation of azygos vein	

Abbreviations: SCA, systemic collateral artery; PA, pulmonary artery; SVC, superior vena cava; RA, right atrium.

SURGERY OF CYANOTIC CONGENITAL HEART DISEASE

Transposition of Great Arteries

The definitive repair for transposition of great arteries (TGA) is usually the total arterial switch procedure (Jatene) replacing the previously done Mustard/Sennings atrial switch which had long-term complications. The current mortality after corrective surgery is between 2% and 5% in the best cardiosurgical centers. **Table 3** gives the evolution of surgical palliation and corrective surgical techniques employed in TGA. Total arterial switch procedure is most successful when done under 2 week of age. In the presence of a large unrestrictive VSD, the corrective surgery is delayed as the LV is conditioned to pump against systemic pressure and resistance. Rastelli procedure is done in TGA complicated by valvar pulmonary stenosis (PS) or left ventricular outflow tract (LVOT) obstruction with VSD, and it involves closure of VSD to the aorta with conduit placed between right ventricle (RV) and PA.

Total Anomalous Pulmonary Venous Connection

The diagnosis is an indication for surgery. Obstructed type of total anomalous pulmonary venous connection (TAPVC) is a surgical emergency. Postoperative results are very good and therefore there is no need to wait, if unoperated. 99% would die within 1 year. Surgery is an open heart operation through a sternotomy, where the pulmonary venous confluence is reanastomosed to the posterior wall of the left atrium.

The mortality of elective surgery of nonobstructed type of TAPVC has been less than 5% in nonobstructive type but the perioperative mortality in obstructed TAPVC may be as high as 20% depending upon the delay in recognition.

Tetralogy of Fallot

The size of the pulmonary annulus will dictate the plan of correction. The branch pulmonary arteries are another determinant to planning repair. If they are good sized, then it is possible to close the VSD and open the pulmonary valve to achieve a complete correction. If not, use of a systemic to pulmonary shunt viz., BT shunt is essential to overcome cyanosis with additional source of blood flow.

Table 3 Transposition of great arteries: palliative and definitive corrective surgeries

<i>Transposition of great arteries (TGA)—Successive modifications in surgical approach (from early palliation to total correction)</i>	
Palliative procedures	
Creation of an atrial septal defect to allow adequate mixing of oxygenated and deoxygenated blood to allow the survival of the infants and neonates for a later corrective surgical procedure	
Blalock-Hanlon procedure	Surgical atrial septostomy
Rashkind's balloon atrial septostomy	Nonsurgical—Miller
Definitive corrective procedures by baffle atrial switch	
Correction of TGA at atrial level employing diversional baffle partitioning the atria so as to direct systemic caval blood to the left atrium and mitral valve into the subpulmonic left-sided ventricle and directing the pulmonary venous blood through the subsystemic right-sided ventricle	
Senning	Use of interatrial baffle designed by cutting and folding of the native atrial tissue
Mustard	Use of atrial baffle created by using Dacron or pericardial grafts
Disadvantages	
Despite initial reported success in long-term survival rates: Long-term baffle related complications, such as sick sinus syndrome, atrial arrhythmias, sudden deaths, progressive tricuspid regurgitation, right ventricular dysfunction and pulmonary hypertension	
Definitive anatomical and physiologic correction of TGA by arterial double switch procedures (switching aorta and main PA)	
Jatene switch	Anatomic corrective operative switch of the transposed great arteries in infants with D-loop TGA to make the left ventricle function as the systemic arterial ventricle Aorta and pulmonary arteries transected, contraposed and anastomosed with reanastomosis of left and right coronary arteries with aortic buttons to the adjacent PA designated to form the neo-aorta
LeCompte maneuver	Used in Jatene procedure to minimize coronary artery kinking
Correction of TGA with VSD and LVOT obstruction	
Rastelli 1969	Sew off main PA; external conduit from right atrium to main PA; baffle directs flow from left ventricle through VSD and out the aorta
Correction of TGA with hypoplastic RV and CHDs sharing similar functional anatomy, e.g., PA arising from dominant LV with aorta arising from rudimentary RV, e.g., tricuspid atresia with TGA, double inlet LV	
Damus-Kaye-Stansel (DKS) Procedure (Initially intended for TGA with VSD)	
Surgical steps of DKS	<ul style="list-style-type: none"> • Division of PA just proximal to its bifurcation; • Creation of tension free end to side PA to aortic anastomosis to bypass systemic outflow obstruction using a prosthetic tube connecting the severed proximal end of PA to the left side of aorta; • Restoration of pulmonary blood flow by: <ul style="list-style-type: none"> – Placement of extracardiac conduit from RV to the distal segment of dissected PA (original DKS procedure) or – As currently done shunt procedures such as: <ul style="list-style-type: none"> - Modified BT shunt mostly in neonates, - BDG (bidirectional Glenn) shunt or extracardiac Fontan procedure in older patients
Result	Early mortality in DKS: 20%
Other problems	Mild pulmonary valve regurgitation (25%); aorta-PA anastomosis narrowing—rare

Abbreviations: LVOT, left ventricular outflow tract; VSD, ventricular septal defect.

Most children are diagnosed soon after birth. If cyanosis is not severe and child is developing and thriving well without cyanotic spell, surgical repair is done between 6 months and 12 months of age. The mortality of surgery of tetralogy of Fallot (TOF) is now about 2–3 %. The surgery involves: (1) patch closure of VSD; (2) resection of RV outflow muscle bundle with or without pulmonary valvotomy or transpulmonary valve annular patch. In the presence of hypoplastic branch of PA, a BT shunt is initially done as a palliative procedure and total correction is done later.

Hypoplastic Left Heart Syndrome

Norwood procedure (3-staged operative procedures in series performed in infants with hypoplastic left heart syndrome [HLHS] to create Fontan circulation) is described in **Table 4**.

LEFT TO RIGHT SHUNTS

Patent Ductus Arteriosus

Indications for Surgical Closure in Patent Ductus Arteriosus

- Endarteritis (50% of deaths in untreated PDA)
- Left atrial or left ventricular enlargement indicating left ventricular volume overload
- PAH or the presence of left-to-right shunting
- PDAs:
 - Calcified
 - Too large for device closure, or
 - Distorted anatomy.

Asymptomatic patients with a PDA are also candidates for closure with a transcatheter device.

Contraindication for Closure

Irreversible pulmonary hypertension with right-to-left shunt.

Timing of Closure

Early closure before 6 months—large/moderate PDA with congestive heart failure (CHF), PAH or with failure to thrive. In infants more than 6 months of age, older and bigger children—a transcatheter device closure/coil occlusion or surgical ligation is done.

Percutaneous Transcatheter Device Closure

There have been many new generations of devices, including improved sheaths and sizes. The Amplatzer PDA occluder can close defects 4–12 mm in size, but smaller residual defects can be occluded with coils. New advances have also provided allowance of confirmation before device release. Temporary test occlusion with a balloon catheter can help with sizing and predict the degree of success. It decreases endocarditis, arrhythmias, and development of pulmonary hypertension. Complications and limitations include residual left to right shunt, incomplete closure, hemolysis, distal embolization, and endocarditis.

Atrial Septal Defect (other than Primum)

Many atrial septal defect (ASDs) are now closed by placement of appropriate sized sandwich occlusive devices such as Amplatzer thus avoiding open heart surgery.

Indications for Surgical or Nonsurgical Device Closure

Atrial septal defect with RV volume overload.

Age of Surgery

Surgical closure for secundum type of ASD is resorted to in children between 2 years and 4 years and it is delayed till 4–5 years of age in sinus venosus defects. Surgical closure earlier than 2 years is undertaken in those rare symptomatic infants at risk of developing pulmonary arterial hypertension (PVR >10 units/m²—contraindication for surgery) often accounting for less than 8% of ASDs, who show evidence of RV volume overload with frequent lower respiratory infections and failure to thrive; and after effectively controlling heart failure and excluding associated defects such as total or partial anomalous venous drainage, aortopulmonary window or LVOT. Surgical mortality is zero. The risk of surgery does not increase with age. However, the operated children must be followed up for years as an occasional child may develop sick sinus syndrome which may necessitate antiarrhythmic treatment or placement of a pacemaker.

Ventricular Septal Defect

Most children with large VSD are diagnosed soon after birth and can have surgical closure after 6 weeks, as the risk of PAH is not changed until this time. Waiting longer in large VSDs is not advisable. Small and moderate ones with no PAH can be kept on observation.

Indications for Surgical Closure

- Moderate to large VSD with uncontrolled CHF; recurrent lower respiratory tract infections or growth failure, markedly enlarged LV in moderate-sized defects (early infancy: 3–6 months); older children with large left to right shunt more than 2:1
- VSDs with near systemic pressures in the RV and PA
- Qp:Qs of 1.5:1–2:1
- Moderate VSD with PA systolic pressure 50–66% of systemic arterial pressure (1–2 years of age)
- Evidence of increased pulmonary arteriolar resistance is an indication for closure (PVR < 8 Wood units with a Qp:Qs > 1.5)
- A drop in PVR to levels less than 8 units after administering oxygen or other vasodilator agents, the patient becomes a candidate for surgery
- Small outlet perimembranous or doubly committed VSDs with associated aortic valve prolapse—early repair (2–3 years of age) to prevent progression of aortic insufficiency after 1–2 yearly follow-up; small VSD with any degree of aortic regurgitation—surgery, whenever AR is detected
- Small VSD with history of infective endocarditis.

Table 4 Norwood procedure (3-staged) for hypoplastic left heart syndrome

Stage I—Objectives	Limitation of pulmonary blood flow Making right ventricle the systemic pump and Ensure interatrial connection
Steps	Division of PA and creation of modified BT shunt or Sano modification; creation of neo-aorta by using PA root as homograft; creation of ASD
Stage II—Objectives	Initiation of separate pulmonary and systemic arterial circulation
Steps	Removal of modified BT shunt and creation of either BDGS or hemi-Fontan
Stage III	Complete separation of pulmonary and systemic arterial circulation

Abbreviations: BT shunt, Blalock-Taussig shunt; ASD, atrial septal defect; BDGS, bidirectional Glenn shunt.

Majority of perimembranous and inlet VSDs are closed via transatrial approach while doubly committed or subpulmonary VSD are best approached via PA under cardiopulmonary bypass. Although majority of VSDs can be dealt with surgical closure, there are situations where surgical closure is not feasible and hence PA banding is done in those situations. Mortality of open-heart VSD surgery has been less than 1% for several years in most centers.

Indications of Pulmonary Artery Banding

Pulmonary artery band procedure as a palliative may be required in the following defects refractory to medical management: multiple *Swiss cheese* VSDs with presence of some remote large muscular VSD, large VSD with straddling AV-valve, and extremely small infants.

Disadvantages of PA banding include early operative mortality, need for two surgeries, subaortic stenosis and technical difficulty involving debanding at time of second surgery.

Catheter Device Closure

Some VSDs are now closed with devices avoiding surgery but it is still in the investigational and evaluation stage in selected centers.

OBSTRUCTIVE LESIONS

Coarctation of Aorta

Intervention is not indicated in children with coarctation of aorta (CoA), if Doppler gradient across coarct segment is less than 20 mm Hg with normal left ventricular function; in all the other children with CoA and a Doppler gradient across coarctation segment less than 20 mm Hg, surgical or catheter intervention is indicated. If mild failure is present, the repair is delayed beyond 3–6 months of age. But in presence of severe cardiac failure, no delay in repair is acceptable.

Timing of Intervention

If repair of CoA is not undertaken before infancy, the incidence of hypertension increases with the time of delay. If repair of CoA is undertaken before 3 months of age, the frequency of restenosis increases. Immediate intervention is warranted in early infancy in presence of left ventricular dysfunction/CHF or severe upper limb hypertension. Surgery is performed beyond 3–6 months of age in mild upper limb hypertension with normal left ventricular function and absence of CHF. In uncomplicated children, intervention can be taken up at 1–2 years of age.

Mode of Intervention

Surgical repair involves resection of involved segment with end-to-end anastomosis, aortoplasty either with prosthetic patch or subclavian flap (Waldhausen repair) or bypass graft placement and is preferred in neonates and infants less than 6 months of age.

The operation is a closed heart surgery, which is done through a thoracotomy. It is very rare to have a coarctation on the right side, which needs a right thoracotomy. There is often a PDA that needs to be ligated at the time of coarctation repair. There is a definitive incidence of recoarctation of 5–10% and this can be treated by balloon dilatation on the second instance.

Percutaneous transcatheter balloon dilatation as a less invasive option is nowadays preferred to surgery for children more than 6 months of age with discrete CoA. Stent placement of appropriate length reduces the incidence of restenosis. Balloon dilatation with stent deployment can be considered in children more than 10 years of age, if required; currently, elective endovascular stenting of aorta is contraindicated for children less than 10 years of age.

Pulmonary Valve Stenosis

- *Mild PS* (gradient < 50 mm Hg): No intervention, only regular follow-up for increasing severity.
- *Moderate PS* (gradient between 50 mm Hg and 79 mm Hg) and *Severe PS* (> 80 mm Hg): Balloon or surgical intervention after stabilization and treatment of CHF.
- *Dysplastic PV with severe PS* in children—surgical valvotomy.

Aortic Valve Stenosis

- *Mild AS* (gradient < 25 mm Hg): No intervention only regular follow-up for increasing severity.
- *Moderate AS* (gradient between 25 mm Hg and 50 mm Hg): No intervention only regular follow-up for increasing severity.
- *Severe AS* (> 50 mm Hg gradient with symptoms or a peak gradient of 70 mm Hg): Balloon intervention is the preferred and rewarding intervention with surgical intervention is resorted to AS with aortic regurgitation or for those with unsuccessful balloon valvuloplasty.

Chapter 40.40

Preventive Cardiology in the Young

S Sivasankaran

Antagonistic pleiotropic theory of aging typically identifies fitness and reproductive success as the prominent life history traits which are achieved at peak adolescence followed by aging and age related disorders. Hence, adolescence is the last opportunity to achieve best cardiovascular health to invest in healthy aging. The Special Turku Coronary Risk Factor Intervention Project (STRIP) study, which evaluated the benefits of lifestyle interventions from weaning, now, forms the scientific foundation for the preventive strategies from infancy.

EVOLUTIONARY FOUNDATION FOR LIFESTYLE INTERVENTIONS

Figure 1 pictorially summarizes the various landmarks in the evolution of human lifestyle.

Figures 1A to G Major landmarks in the evolution of human lifestyle and dietary pattern: (A) Aquatic to terrestrial migration characterized by the evolution of increasing peripheral vascular resistance, the vitamins (C and D) antioxidants and incretin system; (B) Forest fires providing energy dense food makes cooking an integral part of human life; (C) Migration to temperate climate with loss of skin pigmentation; (D) *Agricultural revolution*: Dried seeds (cereals, pulses, nuts and tubers) provided a storage option to overcome famine. Domestication of animals and birds substituted game meat by poultry meat and dairy products; (E) Industrial revolution lead to extraction of salt from sea, sugar from sugar cane, oil from oil seed, and alcohol from fruits, for which human body is least adapted; (F) Modernization provided these energy dense foods in supersizes and feasts whereas the energy needs steadily declined at least by a factor of 5. Stress and tobacco use aggravates the noncommunicable disease epidemic; (G) Hydrogenation bomb refers to the industry mediated popularization of trans-fats along with marketed products, rich in salt, sugar, fat, colors and preservatives, with minimal dietary fiber, and nutrients

(Photo Courtesy: Ms Vasanthy)

The evolutionary biological adaptations to the present human life style can be traced back to major events starting with the aquatic to terrestrial migration of amphibians. The major physiological challenges the animal kingdom faced on this transition were that of gravity and oxidant stress. This necessitated the evolution of many adaptive mechanisms such as the antioxidant systems and antigravity adaptations.

Antigravity Adaptations and Antioxidant System

Loss of buoyancy increases the body weight on aquatic to terrestrial migration. This six-fold increase in body weight necessitated increased peripheral vascular resistance in systemic circulation and higher blood pressure to perfuse tissues and to maintain an optimal perfusion pressure to the cephalad located blood hungry organ, the brain. This is achieved by the further adaptation of the renin-angiotensin aldosterone system and ability to taste salt. Separation of the pulmonary to systemic circulation helped to maintain lower pressure in the pulmonary circuit and made the system more efficient. Evolution of the sunshine vitamin (vitamin D) and its nuclear receptors and healthy, less heavy hollow bones, can be identified as the next landmark. Efficient antioxidant systems helped the animals survive the oxidant stress when the oxygen content increased from 0.5% in water to 20% in the atmosphere. The coevolution of color vision and colored fruits in the plant kingdom facilitated the disappearance of vitamin C synthetic mechanism in primates making them dependent on nutrition for their antioxidant needs. James Lind is credited for the first dietary intervention studies when he saved the life of sailors by providing them with citrus fruits centuries before the discovery of vitamin C. No wonder colored fruits and vegetables are recommended to form half the dietary plate in the current recommendations.

Polar Migration and the Sunshine Deficit

Migration of humans/primates from the equatorial zone towards temperate climate generated fair skin which potentiated vitamin D synthesis by five times making human survival possible at extremes. Epidemiological studies in India have identified vitamin A, vitamin C and vitamin D deficiency to the order of 75% in various segments of the population including children. Studies on vitamin D, vitamin C and antioxidant substitution in adults have not shown any survival benefits. Best bones are achieved at peak adolescence and later supplementation only tries to reduce the rate of bone loss. Indians because of their dark skin synthesize five times less vitamin D and adolescent girls need five times more vitamin D to meet the pregnancy demands. Low maternal vitamin D level correlates with early onset of noncommunicable diseases in the offspring. Providing vitamin D alone is not enough, we need exercise to stimulate the bone growth. Hence, childhood and adolescence is the last opportunity to develop healthy bones as an investment for healthy old age.

Physical Activity

Skeletal muscle is ten times more insulin sensitive compared to adipose tissue and good physical activity is the best way to minimize the onslaught of hyperinsulinemia generated by adipose tissue insulin resistance. Thus, nutrient mediated (insulinogenic) growth predominantly favors adipose tissue growth whereas physical activity (growth hormone) mediated growth builds good muscles and bones. Both isotonic exercise and isometric exercise to lift one's own body weight is essential. Swimming in water can be identified as the most physiologically optimal exercise, avoiding the body weight induced damage to joints. Water provides a good medium for cooling the body and swimming activates both axial and appendicular muscles. Next best place for physical activity

could be the sandy beaches. Gentle breeze keeps the body cool and provides a good resistance for movement. The soft sand acts as the shock absorber to the stress on the joints on walking and jogging.

Traditional Cooking

Provision of energy dense, easily digestible food substances rich in omega-3 fats is considered to be the major factor for primate brain evolution. The shorter gastrointestinal tract of humans mandates cooking as an unavoidable necessity for survival. Good traditional cooking makes food palatable, digestible and nutrient rich. Deep frying destroys the heat sensitive vitamins, polyunsaturated fats and oxidizes the lipid components. Clarified butter (*Ghee*) was demonstrated to be atherogenic because of these oxidation products and hence no longer recommended in diets. Over the last 10,000 years human civilizations flourished, and farming and agriculture evolved as major society achievements. The biological adaptations which evolved slowly further got shattered by the industrial revolutions over the last 200 years.

Agriculture and Poultry Farming

Initiation of agriculture facilitated the use of energy dense pulses, cereals, millets, tubers facilitating social life and efforts to overcome famine. Hydrating these dried seeds during traditional cooking made these products less energy dense. Domesticating animals and poultry farming were the next major dietary changes experienced by *Homo sapiens*. Milk is essentially the secretion from the mammary gland meant for lactation in mammals and the ability to digest lactose is lost at the end of weaning. Human beings modified this genetic programming by repeatedly exposing himself to milk so that now 85% of the population is lactose tolerant. Thus milk and egg along with other animal sources enriched the diet with cholesterol and cholesterol generators. Ancel Keys in his landmark seven country study demonstrated 14-fold increase in cardiovascular mortality as population cholesterol increased from 200 mg/dL to 240 mg/dL. Finland was the first country to embark a comprehensive lifestyle program where people shifted from poultry farming to berry cultivation. Finland was the heart disease capital for the world in 1973 achieved a steady decline in cardiovascular mortality to the tune of 80% by 2007. One of the notable achievements was that the percentage of people using butter along with bread declined from 95% to 5% with a corresponding decline in blood cholesterol levels. Similar decline per capita salt consumption and tobacco use and increasing physical activity were major achievements. Human dietary pattern is omnivorous, but biology is more herbivorous as evidenced by our dependency on vegetable sources for vitamin C and dietary sensitivity to cholesterol. Cholesterol is the steroid for the animal kingdom compared to ergosterols and sitosterols of the plant kingdom. Herbivorous animals can synthesize their need for cholesterol and hence adult humans have an upper limit for their daily cholesterol intake as 200 mg. Poultry farming further changed the dietary pattern from game red meat to fat rich poultry meat. Ordinary egg yolk provides 300 mg cholesterol and a double omelet provides three times the recommended adult dose to a child. Fermentation provided various probiotics and tasty menus, but generation of alcoholic beverages evolved as health menace to mankind.

Insulinogenic Nutrition

It refers to consumption of energy dense food substances and declining physical activity, which favors insulin mediated growth of adipose tissue, obesity and metabolic syndrome. Socialized societies no longer were predated nor faced calamities such as famine. Civilization further harnessed the natural instincts on taste to generate salt from the sea, sugar from sugar cane, oil from

oilseeds, and alcohol from fruit juices. Refining cereals deprived them of their fiber content and vitamins and made them more insulinogenic. Development of beriberi on eating polished rice was demonstrated by Eijkman decades before the discovery of vitamins. This paved the way for nutrition recommendations for the first time.

Consumption of fruit juices is considered equivalent to consumption of one serving of fruits because juicing them makes them more glycemic. Salt evolved as the favorite of the industry because of its ability to preserve food. Further the osmotic challenge induced by the salt makes one consume more sugar sweetened beverages and alcohol. In addition salt provides an acidic challenge. Body fluids contain 140 mEq of sodium and 100 mEq of chloride. Consuming sodium chloride provides equal amounts of sodium and chloride to the body and the excess of chloride provided needs to be buffered by the calcium in the bones leading to osteoporosis and renal stones in susceptible individuals. Recently, concluded HORUS study evaluated Egyptian mummies with computed tomography (CT) scan, demonstrated osteoporosis and vascular calcification in 22 out of 40 mummies below the age of 40 years making atherosclerosis an old disease. Though inflammation was discussed as a possible cause, that period in evolution of mankind corresponds with the popular use of salt by man for preservation. Salt makes the blood vessels stiff. INTERSALT study (an international study of electrolyte excretion and blood pressure) showed that all the six human population who do not use salt in cooking did not have the age-related increase in blood pressure. Naturally salt restriction will have minimum benefit once the blood vessels have stiffened and the studies on adult salt restriction are equivocal.

Fructose and alcohol provide empty calories and aggravate the insulinogenic nutrition, by glucose sparing. Sugar such as cholesterol is not an essential nutrient. Unfortunately, present day children consume five times more sugar than what is recommended, aggravating the damage arising out of insulinogenic nutrition. Though pediatric doses are the rule in pharmacology, supersizing is the rule for bakery products. Biscuits and chocolates were fiber deficient energy dense products initially packed for the soldiers, but their long shelf-life made them the favorite for the industry. Food processing at the industry level makes them more energy dense whereas traditional cooking by hydration lowers the same.

Hydrogenation Bomb

Fat and oils are energy dense cooking medium which make the food tasty and last long in the shelf. Undue frying and reheating generated various oxides and destroys the unsaturated fats and vitamins. Fat transported through chyle directly enters blood and escapes first pass metabolism and avoids incretin release. But when in excess they generate insulin resistance by altering the membrane physiology and glucose sparing such as alcohol and fructose. Trans-fats are highly atherogenic and the favorite for the industry. Long shelf life associated with trans-fats turned out to be the ultimate hydrogenation bomb for mankind. Many countries have banned trans-fats in food and introduced fat taxes to contain the obesity epidemic. Fish and fish oils are cardioprotective but they have lost their nutritive value because of the added salt during preservation and cooking. Deep frying and the bio-accumulated toxins (mercury, lead and pesticides from water) and cholesterol load associated, has made fish no longer heart friendly. Hence, currently fats and oils are recommended to be used only for seasoning which is adequate to meet the essential fatty acid/vitamin need for the body. Currently, urbanized society there is a five-fold decline in energy needs and fried foods are no longer physiological in ordinary diets. The clinical evidences for the mal-

adaptation to our evolutionary programming are represented by sarcopenia, osteopenia, adiposity and metabolic syndrome and their consequence in later life. These evolutionary principles form the sound foundation for the healthy diet plate as illustrated in **Figure 2**.

EPIDEMIOLOGICAL TRANSITION IN INDIA

Autopsy studies in India in 1950s identified atherosclerosis as an uncommon disorder prevalent in old age in India with 15% prevalence in 7th and 8th decade. Corresponding figures showed that the disease prevalence was 45% in 6th decade at Boston. Thus the disease got identified as an outcome of urbanization and westernization. The 1960 epidemiological studies at Chandigarh showed that coronary artery disease prevalence was as high as in Tecumseh in United States establishing the Indian susceptibility to urbanization and westernization.

India has witnessed a steady epidemiological and nutrition transition to evolve as the diabetes and hypertension capital for the world. Both studies on migrants and native Indians have now documented a heavy burden of cardiovascular diseases, almost twice as that of same aged individual in the United States or three times that of Japanese. The diseases occur at least a decade earlier than their counterparts. Younger age escalation of all these diseases and risk factors are documented in population studies as well as from the birth cohort studies. Follow-up data from the New Delhi Birth cohort shows that the incidence of diabetes from the age of 29 to 36 is 1% per year, obesity 2% per year and that of hypertension 4% per year. The increase in risk factors in the

adolescent men is steady whereas in women in the reproductive age group is exponential.

Three patterns of evolution of noncommunicable disease have been noted across the world. Developed countries documented a steady increase in prevalence of the disease as the population aged and with increasing body mass index reflecting gluttony and sloth as the driving forces. Developing nations showed a steeper increase in prevalence of diabetes reflecting additional factors like inflamed fat (adiposopathy) and sarcopenia (lack of skeletal muscle reflected by physical fitness) as the additional drivers. Aboriginal population such the Pima Indians, and Pacific Islanders showed much steeper curve because of the gestational diabetes. Gestational dysglycemia leads to activation of beta cells in utero and premature onset of diabetes in the offspring. The patterns seen in developing countries in India now combine factors for the second and third pattern and hence likely to be worse. Thus the behavioral risk factors in adults has transformed into in utero risk factors for Indians manifesting as gestational obesity, dysglycemia, vitamin D deficiency, hypertension and dyslipidemia and inflammation reflected by skin changes such as acanthosis nigricans. These patterns in increasing prevalence of noncommunicable diseases and risk factors are summarized in **Figure 3**.

CONCLUSION

The driving force for the younger age escalation of risk factors and diseases in India reflects the unhealthy motherhood (in utero

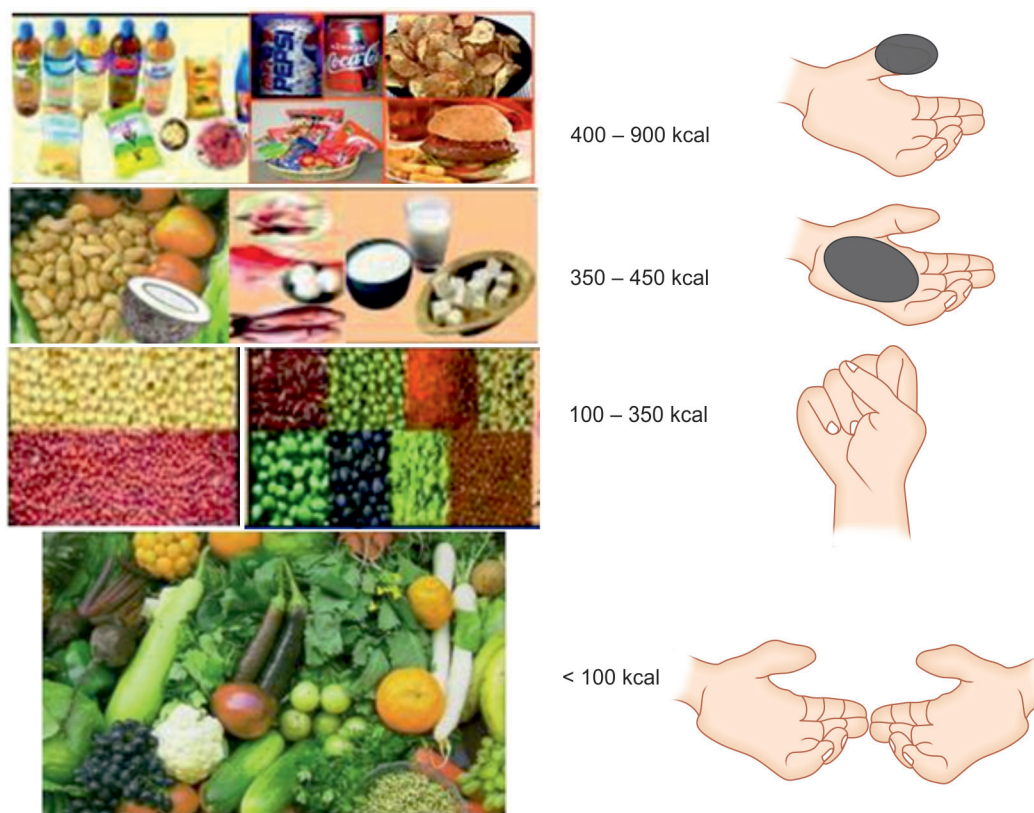

Figure 2 Scientific basis of perfecting a diet plate (kcal/100 g of food). Food substances that are most adapted could form the major plate portion; say hand full of low calorie low glycemic, food rich in dietary fiber, flavonoids and antioxidants represented by colored fruits and vegetables. More energy dense cereals and pulses are limited to hand full food portion and are to be served sprouted or traditionally cooked. More energy dense, nuts, tubers, poultry products need to be limited to a palm size food portion. A pinch of marketed food products are recommended since they are least adapted for optimal health

risk factors) achieved by the Indian girls. Insulinogenic nutrition is characterized by declining energy needs and increasing energy density and glycemia of the food consumed and is least adapted evolutionarily. Poor breakfast and a heavy dinner again reflect a dietary insult when the physical activity is least during the nocturnal sleep. The outcome is exaggerated because of the ethnic susceptibility, sarcopenia, low vitamin D levels and other issues leading to inflammation in Indians. Ecological and

epidemiological basis for the present epidemic is presented to substantiate the fact that noncommunicable disease prevention is a mother and child health priority. Every effort should be made to make children physically active in the sun, and to train them evolve a healthy diet plate for which their physiology is most adapted. **Figure 4** schematically represents the old and new nutrition cycle which drives the nutrition related diseases in India.

Figure 3 Three patterns in the epidemiology of noncommunicable diseases and risk factors noted in the world. The most common pattern seen in developed world is characterized by increasing prevalence of noncommunicable diseases which correlates with increasing age and body mass indices. The second pattern is seen in developing world. Here the pattern is shifted up by adiposopathy (inflamed fat) and sarcopenia, when risk factors occur at lower body mass indices and younger age. The pattern shifts further to left side as the third pattern with early onset of risk factors in offspring or children born to mothers with in utero risk factors as seen in rapidly westernizing and aboriginal population (Pima Indians, Pacific islanders, and Asian Indians) 1

Modified from: Bhattarai MD. Three patterns of rising type 2 diabetes prevalence in the world: need to widen the concept of prevention in individuals into control in the community. JNMA. 2009;48:173-9.

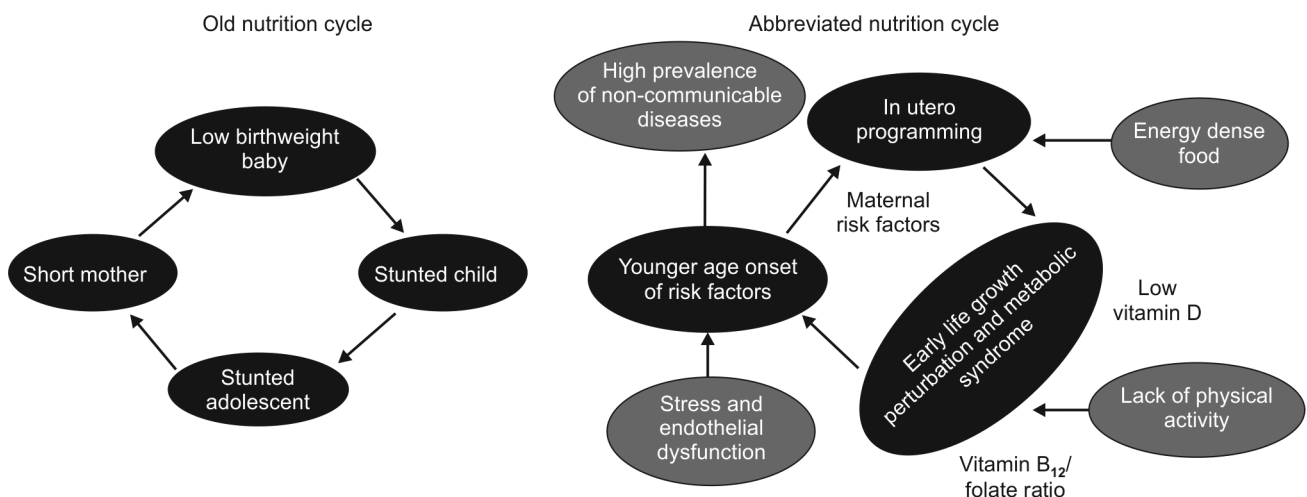

Figure 4 The nutrition cycle, old and new, depicted by the dark ovals and thin arrows. The lighter ovals and short arrows show the drivers and the dark dotted arrow leads to the final outcome. In the old nutrition cycle, vicious cycle generated by stunted mother giving rise to low birthweight baby generated the stunted adolescent and hence mother and child healthcare argued for increasing the nutritional intake to achieve better growth in childhood and adolescence. Simultaneous decline in physical activity and other factors such as low vitamin D levels generated younger age escalation of risk factors. Maternal risk factors adversely program the baby for early onset of risk factors generating the new abbreviated nutrition cycle where the onset of risk factors occur at a younger age

IN A NUTSHELL

1. Childhood and adolescence is the best opportunity to evolve a healthy body composition as an investment for healthy aging devoid of noncommunicable diseases and risk factors.
2. Physical inactivity and unhealthy diet are the major drivers of the noncommunicable disease epidemic in India in children and adolescents.
3. Osteopenia, sarcopenia (less skeletal muscle), adiposity, micronutrient deficiencies and adipocyte inflammation (adiposopathy) are important aspects which predispose the development of metabolic syndrome and noncommunicable disease risk factors.
4. Salt—a no calorie dietary product—which preserves food contributes to the age-related increase in blood pressure and also osmotic and acidic challenge to the body.
5. High increase in oxygen availability at birth necessitates an efficient antioxidant system. Human ability to see colored products is to prioritize colored fruits and vegetables in the healthy diet plate to minimize this oxidant stress.
6. Gravitational increase in body weight necessitates the increase in systemic vascular resistance and development of hollow long bones.
7. Insulin sensitivity of various tissues such as, adipose tissue, liver and skeletal muscle can be modulated by diet, drugs, hormones and physical activity.
